Foreword

During the past half-century, the field of electron transfer reactions has undergone a remarkable expansion. This development began in the middle to late 1940s, with studies of what proved to be the simplest class of reactions in all of Chemistry— isotopic exchange electron transfers in solution. At the same time, new electronic techniques were developed for studying electron transfers at metal electrodes. Before that time, the electrochemical reactions studied involved instead a breaking (typically slow) of chemical bonds and the formation of new ones. Later, isotope exchange reactions were also studied in favorable cases by methods other than those using isotopic labels—for example, by the use of various spin resonance techniques—and became more generally known as self-exchange reactions.

For simple electron transfers no chemical bond is either broken or formed. Instead, only readjustments of bond geometry (distances and sometimes angles) in each reactant, and rearrangements of the likely configurations of the environment, such as solvent molecules, around the reactants are needed. This situation permitted the development of a relatively simple detailed analytic theory for these processes. The resulting equations and their consequences were especially convenient for comparison by experiment, as well as for predicting new results and new relations.

The various experimental studies in these two different fields had stimulated the development of theory, which in turn stimulated new experiments. The further introduction of new technology—lasers for example—expanded the variety of systems which could be studied, ultimately extending to ultra-fast reactions in the pico-second (e.g., photosynthesis) or even the femtosecond regime. Indeed, some of these reactions occur so rapidly that the sluggishness of the solvent (e.g., solvent dielectric relaxation) becomes a rate-controlling or partially rate-controlling factor.

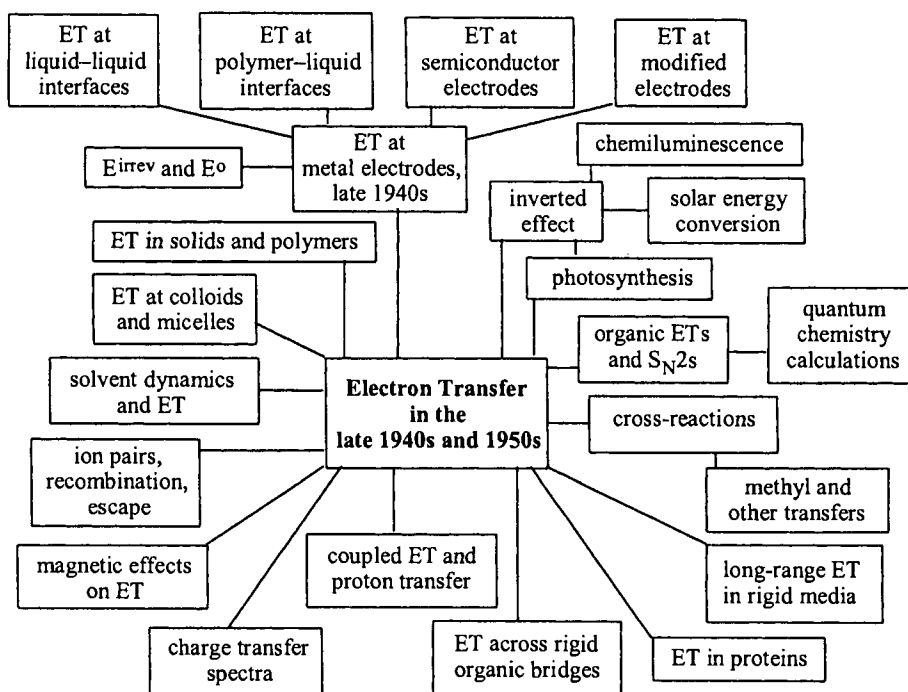

One of the more striking effects to be identified in the field was the “inverted effect,” in which the reaction rate constant k decreased, rather than increased, with increasing “driving force”, namely, increasingly negative standard free energy of reaction, $-\Delta G^\circ$, when ΔG° is very negative. The normal effect is for k to increase with increasingly negative ΔG° , but in the inverted region the opposite is true. As is

well known, some twenty-five years elapsed before this prediction was confirmed experimentally. In the interim, there had been indirect confirmation in the form of the observation of chemiluminescent electron transfer reactions.

There has been much discussion in the literature of electronically adiabatic versus nonadiabatic electron transfers. In the inverted region the electron transfer is electronically nonadiabatic, since it involves a “jumping” from one potential energy surface to another, rather than remaining on a single surface. In the “normal” region the transfer may be adiabatic or, when the electronic coupling of the reactants is weak, nonadiabatic. The parallelism of the maximum in the bell-shaped charge transfer absorption spectrum to the maximum in the k versus $-\Delta G^\circ$ curve is noteworthy. The spectrum to the red of the maximum corresponds to the “normal” region, and that to the blue to the “inverted” region. This parallelism was not realized in the early days (in fact, it may still not be fully appreciated today), but both phenomena have the same origin.

Some of the new theoretical relations, the cross-relation between the rates of a “cross-reaction” of two different redox species with those of the two relevant self-exchange reactions, were later adapted to non-electron transfer reactions involving simultaneous bond rupture and formation of a new bond (atom, ion, or group transfer reactions). The theory had to be modified, but relations such as the cross-relation or the effect of driving force ($-\Delta G^\circ$) on the reaction rate constant were again obtained in the theory, in a somewhat modified form. For example, apart from some proton or hydride transfers under special circumstances, there is no predicted “inverted” effect. Experimental confirmation of the cross-relation followed, and an inverted effect has only been reported for an H^+ transfer in some nonpolar solvents. The various results provide an interesting example of how ideas obtained for a simple, but analyzable, process can prompt related, yet different, ideas for a formalism for more complicated processes.

Eventually, the field grew in many different directions, some of which are shown in the figure below, and many of which were quite unanticipated. This growth is, in retrospect, no longer surprising, since electron transfers have been shown to occur in a wide array of phenomena. The figure is also not comprehensive, and new examples may well occur in the present series of volumes. The understanding and insight gained in the fundamental studies of electron transfers has had a variety of important or potentially important applications, whether in the field of solar energy conversion, nanosized devices at interfaces, batteries, corrosion, respiration, or even the light emission by fireflies.

Professor Balzani and his section editors have made an impressive contribution in bringing together a broad array of interesting topics which now contribute to this dynamic electron transfer field.

Preface

Today, there is barely an aspect of our lives that is not touched fundamentally by Chemistry. We know that Chemistry is *in* us, because our body is composed of atoms and molecules, and functions through the extremely intricate patterns of their interactions. However, Chemistry is also *around* us, in natural phenomena such as photosynthesis, and in the artificial products and materials that sustain the development of our civilization: medicines, fertilizers, plastics, semiconductors, etc. Moreover, the most important global problems—those relating to food, human health, energy and the environment—cannot be solved without the aid of Chemistry.

Chemistry occupies a central position among scientific disciplines, and provides the main links between Biology and Physics. In addition, Materials Science, Chemical Engineering, Earth Sciences, Ecology, and related areas are largely based on Chemistry. And, in the near future our medical problems—and perhaps also our feelings, thoughts, and emotions—will be described and discussed on a molecular (i.e., a chemical) basis. Chemistry, in fact, is far more than a discrete scientific discipline, since its methods, concepts, and practitioners are penetrating virtually all fields of science and technology. Chemistry can, therefore, also be regarded as a trans-disciplinary science that provides an essential means and a fundamental language to understand fully these other scientific disciplines.

A key feature of chemistry is chemical reactivity, and of all the chemical reactions *electron transfer* is undoubtedly the most important. First, electron transfer is the key step in a number of biological processes that have enormous relevance to life, such as photosynthesis and respiration. Second, it is a fundamental feature of many processes of vast technological impact, such as information storage (photography) and energy conversion (batteries). Third, electron transfer is a type of reaction that is amenable to detailed experimental investigation and accurate theoretical descriptions. But perhaps most importantly, the ubiquity of electron transfer in Chemistry and related fields has helped to demolish—and is still demolishing—the arbitrarily created barriers that until now have subdivided Chemistry into its separate organic, inorganic, physical, and analytical branches. In this respect, electron

transfer encourages research at the cross-roads of different disciplines where scientific and technological progress is more likely to occur.

During the past decade, our knowledge of electron transfer has grown at an astonishing rate, and it was for this reason that a need was recognised for a unified view of the field. This Handbook, with its five volumes, 12 parts, and 78 chapters, emphasizes the central role of electron transfer in Chemistry, and reflects the enormously wide range of electron transfer aspects that are currently of interest, from both fundamental and practical viewpoints. The authors of the various chapters have been chosen from among those carrying out the most interesting and forward-looking research in their respective fields. Some chapters, by their own nature, are introductory, others are advanced, and others are focussed on specific theoretical or applicative aspects of electron transfer. Each chapter is enriched by figures and tables that illustrate the topic dealt with in the most convenient way. In addition, since interest in electron transfer processes is moving rapidly towards complexity (artificial supramolecular species, dendrimers, heterogeneous systems, biological systems), several chapters have a large number of structures and schemes.

Volume 1 contains two Parts—the first relating to Principles and Theories, and the second to Methods and Techniques. The first Part (1.1) introduces the reader to the fundamental theories and to the various types of electron transfer processes: adiabatic and non-adiabatic, homogeneous and heterogeneous, one-electron and multi-electron, ground-state and excited-state. The relationship between electron and electronic excitation transfer is also discussed. Part 1.2 includes chapters dealing with the most important methods by which electron transfer processes can be induced and their rates measured: classical methods, electrochemistry, radiation chemistry, and photochemistry. Since many natural and artificial electron transfer processes are induced by light, particular care has been devoted to the description of laser flash photolysis, which is not only the most powerful but also the only technique capable of elucidating the intimate reaction mechanisms of photoinduced processes. Needless to say, knowledge of the theoretical basis of electron transfer processes and of the techniques used most to reveal the presence, to monitor the occurrence, and to measure the rate of electron transfer reactions is a clear requisite for people working in the fields of Chemistry, Biology and Materials Science.

Volume 2 is dedicated to a detailed description of the most important classes of electron transfer reactions involving organic molecules (Part 2.1) and organometallic and inorganic compounds (Part 2.2). In several cases the reactions described are important not only from the viewpoint of fundamental research on reaction mechanisms, but also for their catalytic and synthetic applications. The emerging fields of electron transfer reactions of fullerenes, electron-reservoir complexes, and biomimetic electron transfer chemistry of porphyrins are discussed in depth.

Volume 3 deals with electron transfer in supramolecular systems. Part 3.1 is dedicated to the most important processes that take place in biological systems, from photoinduced charge-separation processes occurring in photosynthesis to electron transfer reactions involving nucleic acids and enzymes. This Part clearly shows that the useful functions performed by biological systems (e.g., solar energy conversion) result from an extremely high degree of organization not only in the space dimension (i.e., in the relative positions of the molecular components partic-

ipating in the process), but also in the dimensions of energy and time. The nine chapters of Part 3.2 discuss electron transfer processes in a variety of artificial supramolecular (multicomponents) systems. Some of these systems (dyads, triads, etc.) have been designed to investigate (and then, to optimize) photoinduced charge separation, which is a fundamental step along the route towards artificial solar energy conversion. Other supramolecular systems, based on hydrogen-bonded self-assembly, have been investigated to elucidate the interplay between electron and proton transfer. Species such as host–guest systems, rotaxanes, catenanes, and dendrimers have revealed new potentialities of electron transfer processes in the emerging fields of fluorescence sensors, molecular-level information processing, and molecular-level machines.

Volume 4 is dedicated to three important topics: Catalysis (Part 4.1), Heterogeneous Systems (Part 4.2), and Gas Phase Systems (Part 4.3). The six chapters of Part 4.1 cover the most important aspects of electron transfer catalysis, from fundamental concepts to organic synthesis, from carbon dioxide fixation to protein catalysis, from redox modulation to biomimetic catalysis. Part 4.2 deals with the basic aspects and the latest developments in electron transfer on semiconductors, dye-sensitized electrodes, mono- and multilayers, intercalated compounds, zeolites, micelles and related systems. Part 4.3 covers gas phase systems, from atoms to small molecules, exciplexes, and supermolecules.

Volume 5 deals more directly with applications of electron transfer, including those already in use, and those at the near horizon. Part 5.1, which is dedicated to the emerging field of molecular-level electronics, reports on the latest developments in the area of nonlinear optics and in the design, construction, and properties of molecular-level wires, switches, rectifiers, logic gates, antennas, and memories. Part 5.2 describes very important applications in the field of imaging and information: photography, electrophotography, photorefractive materials, and photopolymers for imaging. Finally, Part 5.3 deals with applications in the fields of environment and energy, with chapters on solar energy conversion, batteries, and waste remediation.

In general, whilst the chapters of this Handbook focus attention on the developments of recent years, they also place earlier studies in their proper perspective. Therefore the Handbook is intended to serve a joint purpose, both as a reference resource and as an introductory overview, covering practically all kinds of electron transfer processes that occur in Chemistry, from biological systems to materials science. Although the Handbook is not aimed at being a specific lecture course, several sections or chapters can profitably be used as the basis for both advanced graduate and postgraduate courses.

A major feature that emerges from this Handbook is the wide range of perspectives offered by the cross-fertilization of electron transfer research due to its being located at the intersection of Chemistry, Biology, and Physics. Thus, it might be appropriate to ask: in which direction is research in the field of electron transfer heading? In his Foreword, Rudy Marcus suggests that very few of the present-day developments of electron transfer were anticipated when the era of modern electron transfer research began about fifty years ago. He also points out that those developments which did occur were in large part consequences of newly available technologies, such as lasers for pulsed excitation and computers for resolution of X-ray

structures. Whilst new technologies (in particular, nanotechnologies) will certainly orient electron transfer research towards now unpredictable basic aspects and applications, it is clear that three very important fields are likely to benefit from the progress being made currently in electron transfer research, namely the life sciences, artificial solar energy conversion, and molecular-level information processing.

About the Editors

Editor in Chief and editor of Volume III, Part 2

Vincenzo Balzani received his "laurea" in Chemistry at the University of Bologna, Italy, in 1960 and has been Professor of Chemistry at the same university since 1972. He has obtained several awards, including the Canizzarro Gold Medal of the Italian Chemical Society, the Doctorate Honoris Causa from the University of Fribourg, Switzerland, the Ziegler-Natta Lectureship of the Gesellschaft Deutscher Chemiker, the Italgas European Prize for Research and Innovation, the Centenary Lecture of the Royal Society of Chemistry, as well as the Porter Medal on Photochemistry. He is a fellow of the Royal Society of Chemistry, the American Association for the Advancement of Science, and the Italian Accademia Nazionale dei Lincei. He has served or is now serving as a member of the Editorial Boards of several scientific journals, including *Chemistry – A European Journal*, *Chemical Society Review*, *Inorganic Chemistry*, *Nanotechnology*, *ChemPhysChem*, *RSC Dalton Transactions*, and *Accounts of Chemical Research*. He is the author of more than 400 scientific papers, two edited books, and two monographs. His research interests include electron-transfer processes, photochemistry, photophysics, supramolecular chemistry, and artificial molecular machines.

Editor of Volume I, Part 1

Piotr Piotrowiak was born in Wrocław, Poland, and grew up in a small town in the foothills of the Sudety Mountains. He graduated from the University of Wrocław in 1982 (Magisterium with H. Ratajczak). After a brief stay at Stony Brook, he joined the group of G. L. Closs at the University of Chicago, where he received his Ph.D. in 1988. In 1991, after a postdoctoral appointment with J. R. Miller at the Argonne National Laboratory, he took a faculty position at the University of New Orleans in Louisiana, where he became Associate Professor in 1996. Since 1997 he has been an Associate Professor at Rutgers University in Newark, New Jersey. His current research interests include vibronically mediated electron and excitation transfer in compounds with symmetry-forbidden interactions, properties of non-aqueous electrolyte solutions, solvation in mixed media, donor-acceptor systems with heteroatom bridges, and the propagation of electronic interactions across the walls of molecular cages. The work of his group involves the synthesis of model compounds and a variety of time-resolved laser spectroscopy measurements.

Editor of Volume I, Part 2

Michael A. J. Rodgers graduated from the Royal Institute of Chemistry in 1963. In 1964 he received his M.Sc., and two years later his Ph.D., from the University of Manchester. In 1966 he became a postdoctoral fellow at the Lawrence Berkeley Laboratory, later he became a Senior Associate and finally a Lecturer in Chemistry at the University of Manchester. In 1976 he went to the University of Texas at Austin to become Deputy Director and Scientific Coordinator of the Center for Fast Kinetics Research and later Director of that institution. Since 1988 he has been Ohio Board of Regents Eminent Scholar in Photochemical Science and Professor of Chemistry at Bowling Green State University. He held the chair of the department of chemistry from 1996 to 1999. Rodgers has received several awards including the Olscamp (BGSU) Research Award (1996), the American Society of Photobiology Research Award (1997), and he is the 2001 research award winner of the Inter-American Photochemical Society. He has been a visiting professor at the University of Bologna, the University of Puerto Rico (Mayaguez), and at EHICS, Strasbourg. His research interests include excited state dynamics of tetrapyrrole macrocycles, photodynamic and photothermal damage in biological systems, energy transfer involving oxygen, electron transfer in proteins and peptides as well as the design, assembly and use of high-technology instrumentation for transient spectroscopy.

Editor of Volume II, Part 1

Before graduating from high school (Abitur), Jochen Mattay was trained as a laboratory technician (Chemielaborant) at Asta-Werke (Bielefeld). He obtained his diploma (M.Sc.) and later his Dr. rer. nat. (Ph.D.) from the College of Technology at Aachen for his work on synthetic and mechanistic studies of various photoreactions (enones, arenes) under the supervision of H.-D. Scharf. He then spent more than a year as a NATO fellow at Columbia University, New York, where he worked on micellar and magnetic field effects of photocleavage reactions in the group of N. J. Turro. Returning to Aachen in 1980, he started his own projects and finished his habilitation in 1983. In the following year, he was appointed lecturer (Privatdozent). Before joining the chemistry faculty at the University of Bielefeld in 1998, Jochen Mattay held various positions from that of Associate Professor to full Professor at the universities of Aachen (1985–89), Münster (1989–95), and Kiel (1995–98). He also spent some time as Visiting Professor at Osaka University (1995) and at the University of Berne (1996). His research interests include photochemistry, the chemistry of calixarenes and resorcarenes (supramolecular chemistry), fullerene chemistry, as well as stereoselective cycloadditions and radical additions.

Editor of Volume II, Part 2

Didier Astruc is Professor of Chemistry at the Université de Bordeaux I and a Member of the Institut Universitaire de France where he holds the Chair of Supramolecular Organometallic Chemistry. He was born in Versailles and did all his studies in Rennes including his thesis on ferrocene cages under the supervision of Professor René Dabard. He was a NATO post-doctoral fellow at MIT, Cambridge (USA), where he worked with Professor Richard R. Schrock, then took a CNRS position in Rennes and became Maître de Recherche before moving to the Université de Bordeaux I as a full Professor in 1984. He has developed the concept of "Electron-Reservoirs" and its applications, and synthesized with his research group the first organometallic dendrimers. He is interested in supramolecular nanomolecules and nanoscopic materials, and their applications in catalysis, molecular recognition, sensors, and devices.

Editors of Volume III, Part I

Harry B. Gray (on the left-hand side) studied inorganic chemistry at Northwestern University in Evanston, Illinois (1957–60) and at the University of Copenhagen (1960–61) before joining the chemistry faculty of Columbia University, New York. In 1966 he moved to Caltech where he is the Arnold O. Beckman Professor of Chemistry and Director of the Beckman Institute. His research interests include inorganic spectroscopy and photochemistry, bio-inorganic chemistry, and electron transfer in proteins. Jay R. Winkler (on the right-hand side) received his Ph.D. from Caltech in 1984. After a stay at the Brookhaven National Laboratory he moved back to Caltech in 1990 where he is now Director of the Laser Resource Center and a Member of the Beckman Institute.

Editor of Volume IV, Part 1

Shunichi Fukuzumi was born in 1950. He graduated from the Tokyo Institute of Technology in 1973, where he also received his Ph.D. in 1978. After a postdoctoral fellowship with Prof. J. K. Kochi at the Indiana University, he became Assistant Professor at the Department of Applied Chemistry, Faculty of Engineering, Osaka University in 1981. After a stay as Invited Professor at the Department of Chemistry, Marseilles University, he became Associate Professor in 1993 and Professor as Head of the Laboratory of Industrial Physical Chemistry in 1994. Since 1995 he has been Professor at the Department of Material and Life Science, Graduate School of Engineering, Osaka University. Fields of interest include electron-transfer chemistry of biologically important compounds, organometallic compounds, and metal complexes.

Editor of Volume IV, Part 2

Thomas E. Mallouk was born in New York and received an Sc.B. degree from Brown University. He was a graduate student at the University of California, Berkeley, and a postdoctoral fellow at MIT, Cambridge (USA). In 1985, he joined the Chemistry faculty at the University of Texas at Austin. He moved to Penn State in 1993, where he is now DuPont Professor of Materials Chemistry. He is best known for his work on inorganic self-assembly and on the chemistry of layered and zeolitic materials. His research has focused on the application of inorganic materials to different chemical problems, including chiral separations, chemical sensing, photochemical energy conversion, microelectronics, fuel cell electrochemistry, and environmental chemistry. He is author or co-author of approximately 160 scientific publications, including a few good ones, and has also edited three books on chemical sensing and solid state chemistry. He is currently Associate Editor of the *Journal of the American Chemical Society* and serves on the editorial advisory boards of several other journals.

Editor of Volume IV, Part 3

Yehuda Haas was born in Israel in 1939. In 1971 he received his Ph.D. from the Hebrew University of Jerusalem and has been on the staff of the Physical Chemistry Department since 1975, becoming a Professor in 1984. Between 1989 and 1992 he was Vice President for Research and Development of the University. Professor Haas has held several visiting positions at the Max-Planck-Institute in Göttingen (1980), at the University of Southern California in Los Angeles (1981), at the Université de Paris Sud in Orsay (1986), at the Institute of Molecular Science in Okazaki (1992), and at the University of Oxford (1996). His main scientific interests are photochemistry and photophysics, laser-induced chemistry, photo-induced electron transfer, and matrix isolation. His publication list includes more than 120 papers and one book.

Editor of Volume V, Part 1

A. P. de Silva's learning, teaching, and research experiences are a tale of two cities and their universities. The University of Colombo, Sri Lanka, and the Queen's University of Belfast, Northern Ireland, have played host to him alternately. He received his early education in chemistry at Colombo in 1970–75. This was followed by Ph.D. and postdoctoral research in organic photochemistry at Belfast during the period 1976–80. After spending six years lecturing in chemistry at Colombo, he returned to Belfast where he has been lecturer (1986–91), reader (1991–97), and professor since 1997.

Editor of Volume V, Part 2 and Part 3

Ian R. Gould was born in Cleveleys, England, in 1957. He received his M.Sc. in 1978 and, two years later his Ph.D., both with A. A. Gorman at the University of Manchester. After postdoctoral training with N. J. Turro at Columbia University, he became Research Associate there. In 1986 he moved to the Eastman Kodak Company. He has been an Assistant Professor at Arizona State University since 1998. Ian R. Gould has obtained several awards, including the Organic Chemistry Prize (Manchester University), the Gramatacakis Neumann Award (European Photochemical Association), and the C. E. K. Mees Award (Eastman Kodak Company). He is a member of the American Chemical Society, the Inter-American Photochemical Society, and the European Photochemical Association. His research interests include organic photochemistry and photophysics, fundamental mechanisms of electron- and proton-transfer reactions, photonic materials, biopolymers, reactions of organic radical ions, spectral sensitization of semiconductors, fast reaction kinetics, and pulsed laser techniques.

List of Authors

Authors for Volume I

Ann-Margret Andersson
Department of Chemistry
Tulane University
New Orleans
Louisiana 70118
USA

Andreja Bakac
Ames Laboratory
Iowa State University
Ames
Iowa 50011
USA

David N. Beratan

Part 1

Principles and Theories

1 Electron Transfer: Theoretical Models and Computational Implementation

Marshall D. Newton

1.1 Introduction

Electron transfer (ET) plays a central role in a broad array of processes in the physical, chemical, and biological sciences [1–10]. These processes are of interest in a rich variety of environments, ranging from the gas phase to homogeneous and inhomogeneous condensed-phase media (e.g., at surfaces modified by self-assembled films), and their description involves a number of fundamental issues in chemical energetics, dynamics, and geometric and electronic structure. In spite of the complexity of these issues, it should be noted that the seminal theoretical contributions of Marcus and the Russian school nearly half a century ago [11] have successfully passed the test of ever-increasing experimental scrutiny and remain a vital force in guiding current research, as made clear in a number of recent reviews [1–10]. Complementing the models for thermal ET, the approach of Hush for treating optical electron transfer [12] has led to an extended framework, often referred to as the Marcus–Hush theory.

Present-day mechanistic understanding of electron transfer is reflected in theoretical models of rapidly expanding sophistication [13–21]. A major driving force in the evolution of these theories has been the need to respond to the challenges posed by the spectacular advances in experimental capabilities in recent times [1–5, 10, 22–29] (e.g., ultrafast laser probes and techniques in synthesis and assembly). The theoretical models play two important complementary roles: (1) leading (in conjunction with modern computational techniques and computing power) to realistic computational implementation; and (2) allowing analysis of the results of such calculations (as well as those from experiment) in terms of compact predictive models grounded in simple concepts of chemical structure and bonding. The power of the current array of theoretical tools for elucidating the details of ET dynamics is underscored by their typically generic applicability: for example, to ground-state or photoinitiated processes [30], both homogeneous and interfacial [31–33]. The continuing goal, of course, is to convert the rapidly accumulating mechanistic infor-

mation about ET processes (often representable in terms of simple rate constants) into precise tools for fine-tuned control of the kinetics and for design of molecular-based systems which meet specified ET characteristics. In the remainder of this paper, unless specified otherwise, the label “ET” is used generically to refer to electron-, hole-, or hybrid one-particle transfer [34].

Current theoretical techniques permit detailed treatment of the various electronic and heavy-particle modes of complex ET systems (including both discrete solute species and surrounding medium) at quantum mechanical, semiclassical or classical levels, as dictated by the nature of the relevant competing timescales [13, 14, 16, 19, 20, 35]. Typically (e.g., see [1]), one identifies and quantum mechanically treats the electronic manifolds of the local molecular donor (D) and acceptor (A) sites, and then formulates the manner in which the effective coupling facilitating the ET process is mediated by the energetic and electronic features of the intervening medium (the “bridge” B) as well as the surrounding environment. The energetics and dynamics associated with activation are treated with either classical or quantum mechanical models. Large-scale molecular dynamics (MD) or Monte Carlo (MC) computer simulation studies are playing an increasingly valuable role in probing mechanistic details at the molecular level (e.g., [15, 33, 36, 37]).

A generic DBA system is schematically depicted in Figure 1, showing examples of coupling of the intramolecular (e.g., where D and A are covalently linked by a molecular bridge B) and intermolecular (e.g., where the “bridge” B could be solvent)

Figure 1. Schematic depiction of a generic DBA system, comprised of local donor (D) and acceptor (A) sites, the intervening bridge (B), and the surrounding medium (e.g., solvent). In the two-state approximation (TSA), ET kinetics for the $\text{DBA} \rightarrow \text{D}^+\text{BA}^-$ process may be modeled in terms of initial- (Ψ_i) and final-state (Ψ_f) wavefunctions, in which the transferring charge is localized primarily on the D and A sites, respectively. In the case of electrodes (e.g., metal or semiconductor), where multiple electronic states are involved, the D and A sites may still be taken to be localized and to involve atomic sites of the electrode near the site/or sites of attachment or contact with the bridge); SAM \equiv self assembled monolayer; STM \equiv scanning tunneling microscopy.

types. Figure 1 also provides examples in which the localized molecular D and A sites are replaced by electrodes. In these situations, one may still be able to identify effective local D and A sites near the points of attachment or contact between the electrodes and the bridge, but one must take due account of the special features of the electrodes (e.g., density of states and spatial delocalization of metallic orbitals) [38]. As noted below, electron transfer ($\text{DBA} \rightarrow \text{D}^+\text{BA}^-$) is one of several related processes of interest involving bridge-mediated D/A coupling.

The flavor of the diversity in current ET research can be appreciated by noting a number of recent advances which serve to broaden perspectives about underlying electron-transfer mechanisms. These developments have benefited especially from ultrafast laser pump/probe experiments [1, 2, 23, 24, 39–42], which have opened up a broader and better-controlled dynamic range, thus forcing the community to address a number of new issues related to the nature of the interacting states and the dynamics of their evolution.

Photoinitiated and optical electron-transfer processes and their relationship to corresponding ground-state thermal processes provide important new tests of theory, especially when comparisons are made: for a given DBA system, of charge separation (CS) and charge recombination (CR), or of thermal and optical electron transfer (e.g., [27]). Photoinitiated processes have also been valuable in providing access to the dynamics of electron transfer in the “activationless” and “inverted” kinetic regimes (e.g., [43, 44]).

Relative to the simple classical kinetic model based on a single-solvent reaction coordinate [11a] (still useful in many situations, e.g., [27]), ET dynamics is now generally recognized [1, 10, 13, 14, 16, 24, 43, 44] to involve a wide range of time-scales (both high- and low-frequency modes, and relaxation processes spanning the limits of fast inertial and diffusive, strongly overdamped response), governing a number of solvent and molecular coordinates. Despite the complexity of ET dynamics (often nonexponential), rate constants and associated rate-determining steps may be identified in limiting cases (e.g., under steady-state conditions [8] or as discussed in [13a]). The transition-state kinetic model for electronically adiabatic ET (i.e., strong D/A electronic coupling), once thought to be superseded in most cases by overdamped solvent dynamics, is now recognized to be a much more subtle and complex issue [35].

Long-range ET between a given D and A site may involve a direct coherent (e.g., superexchange) process or an incoherent (or possibly coherent [45]) stepwise process, depending on the trade-offs governed by the electronic coupling and energy gaps of the DBA system and by electronic relaxation due to the medium [19, 46].

Theoretical formulations of reorganization in the course of electron-transfer processes have undergone a number of advances in recent years. The relative importance of various solvent contributions (including translational as well as orientational response, and inductive and dispersion as well as electrostatic interactions) can depend strongly on the polarity (i.e., dipolar, higher multipolar, or nonpolar) as well as other molecular features of the solvent [21, 47–49]. Molecular-level perspectives on solvent response are of great utility in helping to parameterize effective cavity models (e.g., in conjunction with conventional [50] or spatially nonlocal [47] dielectric models). Additivity relationships traditionally assumed to pertain to sol-

vent and molecular (“inner sphere”) reorganization energy [8] are coming under new scrutiny, as the role of solvent-driven cavity fluctuations begins to receive attention [51]. (These are distinct from the traditional “inner-sphere” fluctuations governed by the coordinates of the DBA solute [8, 9]). The possibility of the effective cavity sizes being appreciably frequency-dependent, corresponding to different frequency domains of the medium response has also been considered in recent studies [52]. A particularly interesting consequence of the new, molecular-level understanding of medium reorganization is the prediction [21] and recent experimental confirmation [53, 54] of sizable entropic components of solvent reorganization free energies, with sign (positive) opposite to that predicted by standard continuum models for solvents of moderate or high polarity. Other molecular-level features of reorganization involve specific solvation effects (inferred from solvent-dependent “inner-sphere” energetics [24, 55]). The possible influence of ion-pairing or other aspects of finite ionic strength on solvent reorganization energy has also been considered [56, 57], but with indications that the effect is likely to be small. Analysis of resonance Raman data has recently become a rich source of mode-specific molecular as well as solvent contributions to reorganization energy [55, 58, 59].

Traditional models of D/A coupling in ET processes have generally been cast in terms of a two-state framework based on charge-localized diabatic states. A recent generalization [30] of the Mulliken-Hush model [12] has provided a complete prescription of the diabatic basis and associated D/A coupling entirely in terms of adiabatic state information (e.g., experimental spectroscopic data or data based on calculated eigenstates). This approach yields a natural definition of effective D/A separation distance and can be easily extended to accommodate an expanded electronic framework in situations where the two-state level is inadequate. Calculation and superexchange analysis of D/A coupling has yielded correlations of coupling element signs and magnitudes within families of DBA systems, and numerous instances of interference among multiple superexchange pathways (both constructive and destructive) have been identified [4, 6, 10, 27, 34, 60–64].

In spite of the utility of formulations based on diabatic states, especially for ground-state thermal processes, it has recently been argued [65] that for some cases of initial states prepared by photoexcitation, an adiabatic basis and associated non-Born–Oppenheimer (BO) coupling must be adopted in accounting for electron-transfer dynamics. Other manifestations of departures from the simple BO framework and the Condon approximation [66] are the appreciable sensitivity of D/A coupling magnitudes to fluctuations in various intra- and intermolecular coordinates [60, 67–70], and the frequent need to supplant a model cast in a purely electronic framework (with its convenient symmetry-based selection rules) with a more general vibronic model in which “intensity borrowing” becomes increasingly likely as the density of vibronic states increases [71].

Looking at the broader context of long-range D/A interactions (see Figure 1), we emphasize that aside from the already rich and complex domain of electron- and hole-transfer kinetics, there is rapidly accelerating interest in related phenomena such as electronic conductivity (especially in nano- and subnano-scale systems) [3, 38, 72], STM [3, 72b], and electron transmission through thin films [73], all quasi-one-particle processes, and excitation-energy transfer [26, 62, 74–76] and magnetic-

[28, 77, 78] and double [6, 79] exchange, quasi-two-particle processes. When both D and A sites have paramagnetic “cores”, the D/A coupling elements become spin-state dependent [77].

Another area of increasing emphasis is the elucidation of chemical bonding rearrangements either initiated by or accompanying ET; for example, coupled proton– (or other ion–) electron transfer (*cpet*) [20, 22] and dissociative ET [80]. Such a focus, of course, lies at the heart of much current research in solar-energy conversion. An especially exciting recent development is the construction of a functioning biomimetic photon-driven proton pump [81].

Against the above background, the primary objective of this chapter is the illustration of some of the current techniques exploited in the theoretical formulation and computational implementation and analysis of ET in complex molecular aggregates; it will be shown how the control of the kinetics (e.g., enhancing desired processes, while inhibiting others) is established by the interplay between system dynamics, energetics, and coupling magnitudes. In the following sections we deal, in succession, with phenomenological kinetic schemes and microscopic formulation of rate-constant expressions, associated aspects of energetics (activation parameters and reaction coordinates), and effective D/A coupling. We then consider a number of tests of theoretical models based on direct comparison of experimental data or detailed computational studies, and offer examples of the extent to which meaningful contact can be established between theory and experiment. Complementary in-depth treatments of many of the topics touched on here are offered elsewhere in this series.

1.2 Kinetic Schemes

As a prelude to a detailed consideration of microscopic rate constants, we discuss a number of ET processes of current interest in terms of simple kinetic schemes; the insights gained by invoking a steady-state model are emphasized [8]. The following equation represents a simple picture of activated ET:

where the reactants (DBA) in their equilibrium (R) and activated (R^\ddagger , the transition state) states are connected by rate constants a and b , and passage (assumed irreversible) to products ($P \equiv D^+BA^-$) is governed by rate constant c . At the level of steady state for the intermediate R^\ddagger (valid for sufficiently long times if the condition $a/(b+c) \ll 1$ is also satisfied) [82], k_{et} is given by the so-called mean-first-passage (*mfp*) rate constant, k_{mfp} [83], where:

$$\dot{P} = k_{mfp}R \quad (2)$$

and

$$k_{\text{mfp}} = ac/(b + c) \quad (3)$$

For sufficiently fast consumption of R^\ddagger to form product ($b \ll c$), the rate-determining step is the activation process governed by $k^{\text{act}} \equiv a$. On the other hand, in the opposite limit ($b \gg c$), the ratio of R and R^\ddagger is maintained at the equilibrium value and transition state theory (TST) may be employed. Now the $R^\ddagger \rightarrow P$ process is the rate-determining step:

$$k_{\text{et}} = k^{\text{TST}} \equiv (a/b)c \quad (4)$$

We note that k_{mfp} (Eq. 3) has the form expected for two kinetic processes in series:

$$1/k_{\text{mfp}} = 1/k^{\text{TST}} + 1/k^{\text{act}} \quad (5)$$

To place the mfp approach in a broader context, we now extend Eq. 1 to deal more explicitly with the ultimate formation of equilibrated product P [83]. In the case of weak D/A coupling, where a diabatic basis comprised of charge-localized valence-bond structures may be employed to represent the relevant states of the reacting system, the “first-passage process” can be viewed as the conversion of the activated reactants (R^\ddagger) to the resonant state of activated products (P^\ddagger); subsequently P^\ddagger may “recross” to R^\ddagger (i.e., pass back through the hypersurface in configuration space defining the transition state) or proceed irreversibly to P :

The overall steady-state rate constant k_{et} (cf. Eq. 3) is given by [83],

$$k_{\text{et}} = k_{\text{mfp}}/[(b/b')(k_{\text{mfp}}/a) + 1] \quad (7)$$

where we assume $c = c'$. Among interesting limiting cases, we note that for “slow passage” ($c \ll b, b'$),

$$k_{\text{et}} = k^{\text{TST}} \quad (8)$$

as given by Eq. 4. In the limit of slow activation (where $k_{\text{mfp}} = a$),

$$k_{\text{et}} = k_{\text{mfp}}/2 = a/2 \quad (9)$$

In Eqs. 8 and 9 we take, for simplicity’s sake, the limiting case, $b = b'$. The factor of $\frac{1}{2}$ underscores the importance of successful deactivation as well as activation. In the case of appreciable D/A coupling, where diffusion occurs across an activation barrier of appreciable extent, diffusive or TST limits may also be obtained [84].

Steady-state models analogous to those introduced above may also be applied to more complex situations involving sequential activation processes, for example, activation with respect to inertial or diffusive medium modes, followed by activa-

tion involving inertial molecular modes [8, 85]. For example, a scheme following Eq. 1 corresponds to a special limiting case of the kinetic model of Sumi and Marcus (SM) [13a], in which a and b govern diffusion in a solvent reaction coordinate, and c denotes a TST rate constant (for a fixed transition state value, a point “sink,” of the solvent coordinate) involving an inertial low-frequency molecular coordinate. In general, the SM kinetic model includes contributions from a finite distribution of values of the solvent coordinate.

A scheme following Eq. 1 is also of value for dealing with sequential (incoherent) ET processes (k^{seq}) in DBA systems, for comparison with competing direct (coherent superexchange) processes (k^{se}). Recasting Eq. 1 gives, for example,

where (D^*BA) is a photoexcited state (e.g., as in the initial ET event in bacterial-photosynthesis (BPS) [78]) and the second sequential step c is assumed irreversible. In the limit of $b \ll a, c$ (which may be justified in terms of arguments based on relative density-of-states and reaction exothermicities [19b, 78]), the steady-state result for the overall sequential process is simply $k^{\text{seq}} = a$ (which may be compared with k^{se} [78]), and the steady-state ratio of $(\text{D}^+\text{B}^-\text{A})$ and D^*BA is a/c , a result similar to that obtained for BPS by Marcus using a more detailed treatment [78a] (Marcus has also discussed a related sequential process which is coherent [45]).

As part of a general study of electron transfer through molecular bridges, Bixon and Jortner examined sequential electron transfer in terms of a somewhat extended kinetic scheme [19b]:

They neglected the reverse rate governed by b (assuming an exothermic initial step) and assumed rapid nonradiative relaxation of nascent D^+BA^- (governed by rate constant e). The steady-state result once again identifies the charge injection process as the rate-determining step (i.e., $k_{\text{et}} = a$) under the conditions $d \ll e$.

A similar picture has emerged from analysis of experimental data by Davis et al [86]. Charge injection (first step in Eq. 10), may be rate-determining in an overall incoherent sequential process when the charge-injection step is quasi-thermoneutral, whereas for appreciably endothermic injection (large positive gap), coherent superexchange dominates (governed by d in Eq. 10). For sequential ET in sufficiently extended bridges (with many intermediate sites), the weakly distance-dependent diffusive hopping within the bridge is eventually expected to become the rate-determining step [19a, 19c].

In related model studies [19a], the competition of parallel sequential and superexchange processes was studied in terms of the dependence of the steady-state rate constant on magnitudes of nearest-neighbor D/A coupling, gap-separating D/A

and bridge levels, and dephasing (represented by a Bloch-type phenomenological model):

$$k_{\text{et}} = k^{\text{seq}} + k^{\text{se}} \quad (12)$$

The occurrence of sequential and superexchange ET processes in parallel has also been discussed in detail in [19b]. In this formulation, the intermediate species ($\text{D}^+\text{B}^-\text{A}$ in Eq. 10 is not required to be thermally relaxed.

1.3 Rate-Constant Models

As illustrated in the previous section, the kinetics associated with an ET process may be complex when diffusion or relaxation processes create dynamic bottlenecks. In limiting cases, however, a simple model based on transition state theory (TST) suffices. According to TST, the system maintains thermal equilibrium between different positions along the reaction coordinate [87]. We consider the TST rate constant for electron transfer after some preliminary comments about state manifolds and energetics.

1.3.1 System Hamiltonian and Electronic States

The rate-constant models considered below depend ultimately on the Hamiltonian adopted for the DBA system of interest:

$$H = H^n + H^{\text{el}} \quad (13)$$

where H^{el} is the electronic Hamiltonian (including electronic–nuclear interactions) and H^n is the nuclear kinetic energy operator. In the spirit of the Born–Oppenheimer approximation (BOA), system wavefunctions may be taken as simple “vibronic” products of electronic (ψ_{el}) and nuclear (χ_n) wavefunctions (vibrations, rotations, etc). Under the BOA, an ET process may be viewed as *adiabatic*—that is, occurring on a potential energy surface associated with a *single* electronic state, ψ_{el} . On the other hand, breakdown of the timescale separation underlying the BOA leads to a *non-adiabatic* process, involving two or more electronic states and their associated energy surfaces [8].

An adequate account of many ET processes of interest is provided by the so-called two-state approximation (TSA), according to which the dynamics of ET is assumed to be adequately accounted for by the two-component space (denoted as the D/A space) spanned by states in which the transferring electron is primarily confined to the D and A sites [6, 60]. (When one or both of the two states are degenerate or near-degenerate, a somewhat more elaborate “two-level” model must be adopted [60].) In general, the two-state approximation is only valid if the gap

between the intermediate electron-transfer states involving the bridge from those of the D/A space is large relative to the strength of the coupling of D and A to the bridge [88]. While the basis set for representing the D/A space is to a large extent arbitrary, convenience generally dictates the choice of either the appropriate adiabatic states (i.e., those which diagonalize the electronic Hamiltonian of the system, H^{el}), denoted ψ_1 and ψ_2 , or the “diabatic” states ψ_i and ψ_f , related to ψ_1 and ψ_2 by a unitary transformation,

$$\psi_1 = \cos \theta \psi_i + \sin \theta \psi_f \quad (14a)$$

$$\psi_2 = -\sin \theta \psi_i + \cos \theta \psi_f, \quad (14b)$$

defined operationally so as to correspond optimally to the actual (nonstationary) states presumed to be involved in the dynamic process underlying the electron-transfer kinetics [6, 60].

For ET initiated in ground-state systems, ψ_1 and ψ_2 will generally be the two lowest-energy adiabatic states, whereas higher-energy states will be involved in photoinitiated ET [89]. We emphasize that the definition of ψ_i and ψ_f is never unique [30b], and the utility of a given prescription must ultimately rest on the results of detailed applications. In typical situations, ψ_i and ψ_f correspond to charge-localized valence-bond structures (e.g., DBA and D^+BA^-). Such structures, aside from their chemically intuitive appeal, also have the advantage that their coupling is dominated by the electronic Hamiltonian, with only minor non-Born–Oppenheimer coupling (i.e., from the nuclear momentum operator) expected [8]. In some situations, however, especially those involving photoinitiated ET in cases of strong D/A coupling, the initially prepared states may involve significant mixing of charge-localized states (e.g., [39]). A criterion for defining maximally charge-localized diabatic states in terms of dipole-moment matrix elements will be presented in Section 1.4 of this chapter.

In thermally activated ET we are interested in the electronic states at the transition state (TS). When the system is at equilibrium in either the initial or final state (where D and A are well out of resonance), the diabatic states, ψ_i and ψ_f , can be taken to be essentially the same as their adiabatic counterparts, ψ_1 and ψ_2 . When the system with weakly coupled D and A is suddenly carried into the TS by a fluctuation, we adopt the picture that the system remains in the (now nonstationary) ψ_i state until (with some finite probability) it dynamically “tunnels” (see below) to ψ_f and irreversibly relaxes to the equilibrium product. The required resonance of D and A is a statement of the Franck–Condon control of thermally activated electron transfer [6, 8, 60]; that is, at the TS,

$$\langle \psi_i | H^{\text{el}} | \psi_i \rangle = \langle \psi_f | H^{\text{el}} | \psi_f \rangle \quad (15)$$

and that this electronic energy matches will be central to some of the models for D/A coupling given below (i.e., those pertinent to thermal ET). Of course, vibronic effects allow some departure from strict electronic energy matching in thermal processes.

In optical electron transfer, the photon energy helps to balance the electronic mismatch associated with vertical excitation from equilibrium, where, as noted

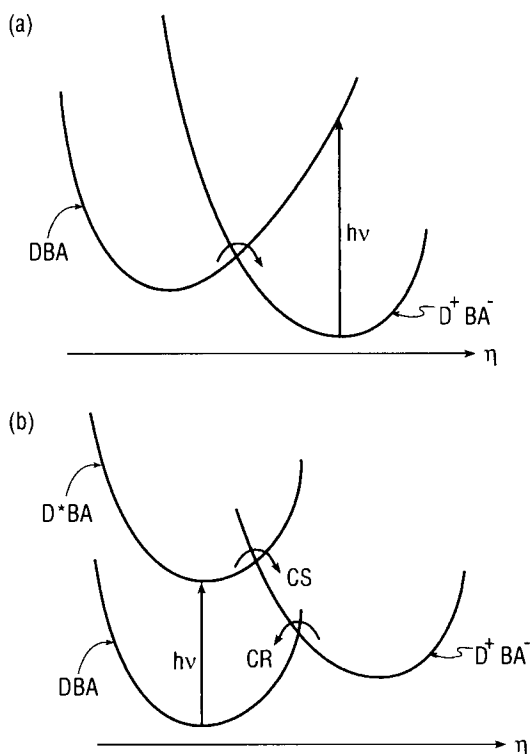

Figure 2(a). Schematic representation of optical- and thermal ET, corresponding, respectively, to the vertical transition with excitation energy $h\nu$ and passage through the transition-state (or crossing) region. In experimental studies, the thermodynamically stable state, which is the *final* state in the *thermal* ET process, generally serves as the *initial* state in the corresponding *optical* process. **(b)** Sequence of photoinitiated electron transfer: charge separation (CS) from a locally excited state, followed by charge recombination (CR) back to the ground state. The CS, CR notation is generally limited to cases where the D and A sites are initially charge neutral (as drawn).

above, the distinction between adiabatic and diabatic states is typically minor for weakly coupled D/A sites (for exceptions in the case of strong D/A coupling, see, e.g., [39]). The formulation of effective D/A coupling for the nonresonant optical electron-transfer process is generally different from that employed for thermal (resonant) electron transfer [6, 89], as discussed in Section 1.4 of this chapter.

Examples of ground-state and photoinitiated ET and optical ET are illustrated schematically in Figure 2 in terms of energy profiles along a reaction coordinate (η), according to the TSA, in which each process involves a pair of electronic states. The nature of the energy profiles and reaction coordinates will be discussed below. The cases displayed include:

- 1) Ground-state thermally activated ET proceeding through the transition state (TS) in the crossing region (Figure 2a); the designation “ground-state” indicates that the TSA involves the two lowest-lying states of the system.
- 2) Optical electron transfer (often designated “intervalence transfer,” IT, in the case of binuclear mixed-valence transition metal complexes [6, 12]), occurring vertically from the equilibrium configuration of the initial state (Figure 2a).
- 3) Photoinitiated ET (following initial photoexcitation, typically to a locally excited non-charge-transfer state), involving charge separation (CS), followed perhaps

by subsequent photochemistry (not shown) occurring in competition with charge-recombination (CR) back to the ground state (Figure 2b). The photo-initiated ET will be a thermal process, provided the vibrational relaxation of the initially excited states is sufficiently rapid. The notation CS and CR is generally applied to situations in which D^* and A (or D and A^*) are charge-neutral groups (e.g., [90]). When, for example, the species D^* has a negative charge, the $D^*BA \rightarrow D^+BA^-$ process is frequently referred to as a charge-shift (CSH) reaction.

1.3.2 Diabatic Energy Surfaces

The energetics needed to characterize ET between weakly coupled diabatic states, ψ_i and ψ_f , can be expressed in terms of free energy quantities based on the Hamiltonians for nuclear motion (H_i and H_f) at the level of the BOA [47],

$$H_y = H^n + V_y; y = i, f \quad (16)$$

where the effective potential energy, V_y , is given by the expectation value of H^{el} (already introduced in Eq. 15),

$$V_y \equiv \langle \psi_y | H^{\text{el}} | \psi_y \rangle; y = i, f \quad (17)$$

The equilibrium free energies G_i and G_f are then expressed in terms of partition functions, Z ,

$$Z_y \equiv \exp(-G_y/k_B T) = A \int d\{Q\} \exp(-H_y/k_B T); y = i, f \quad (18)$$

where $\{Q\}$ denotes the set of nuclear coordinates, k_B is the Boltzmann constant, and A is a proportionality constant. The net free energy of the ET process is given by the following equation:

$$\Delta G^\circ = G_f - G_i \quad (19)$$

To formulate non-equilibrium free energies such as the activation (G^\ddagger) and reorganization (λ) free energy, we consider *constrained* free energies, $G_y(\eta)$, based on imposed configuration space relations of the type represented below:

$$f\{Q\} = \eta \quad (20)$$

where η is an arbitrary constant. A single collective ET reaction coordinate is often defined in terms of the vertical potential energy difference,

$$f(\{Q\}) = \Delta V_{if} \equiv V_f - V_i \quad (21)$$

The probability of ΔV_{if} having a value η is proportional to:

$$\exp[-G_r(\eta)/k_B T] = B \int d\{Q\} [\exp(-H_r/k_B T)] [\delta(\Delta V_{if} - \eta)];$$

$$r = i, f \quad (22)$$

where B is a constant common to states i and f and δ is a Dirac delta function. The $G_r(\eta)$ quantities are denoted as potentials of mean force and serve as the effective potential-energy functions governing the electron-transfer process. From Eq. 22, Eq. 23 can be derived [91]:

$$G_f(\eta) = G_i(\eta) + \eta \quad (23)$$

and hence $G_i(\eta)$ and $G_f(\eta)$ have identical curvatures with respect to η at a given η value. The reaction coordinate can be identified with the continuous variable η , or some linear function of η [13, 47, 83, 84, 91]. In general, such a coordinate will define a reaction path quite distinct from alternatives such as a steepest-descent path on an adiabatic energy surface (e.g. [9c]).

Some important free-energy relationships are presented in terms of the diabatic energy profiles G_i and G_f in Figure 3. The vertical and horizontal shifts of the G_f profile relative to that for G_i correspond, respectively, to the driving force of the ET process ($-\Delta G_{if}^\circ$) and the reorganization energy (λ) of nuclear modes (shifts of equilibrium coordinate values).

As drawn, Figure 3 corresponds to the “normal” regime, $-\Delta G_{if}^\circ < \lambda$, where the diabatic crossing (the transition state) occurs between the reactant and product minima along the η coordinate. This is in contrast to the “inverted” regime, where $-\Delta G_{if}^\circ > \lambda$. Practical details concerning the evaluation of $G_i(\eta)$ and $G_f(\eta)$ have been discussed, for example, in [92]. The vertical gaps at the initial (η_i) and final (η_f) state minima are, respectively, η_i and $-\eta_f$ (defined in this manner, both gaps are positive for the normal regime depicted in Figure 3), and the corresponding reorganization free energies for the initial and final states are given by Eqs. 24a and 24b [47]:

$$\lambda_i = G_i(\eta_f) - G_i(\eta_i) \quad (24a)$$

$$\lambda_f = G_f(\eta_i) - G_f(\eta_f) \quad (24b)$$

Thus, for a given diabatic state, λ is the free energy difference between the minimum energy point and the point corresponding to the minimum energy of the other state. The effective λ value for the two-state system can be taken as the arithmetic mean of λ_i and λ_f [47] (i.e., one-half of the Stokes shift for the optical ET process).

The diabatic crossing occurs at $\eta = \eta^\ddagger = 0$ (i.e., $G_i(0) = G_f(0)$), yielding the diabatic activation free energy,

$$G_i^\ddagger = G_i(0) - G_i(\eta_i) \quad (25)$$

Figure 3. Effective energy profiles along the reaction coordinate (η) for the initial and final diabatic states, indicating the reorganization energy (λ), activation-free energy (G^\ddagger), and reaction driving force ($-\Delta G^\circ$). In a linear system, with parabolic profiles of equal curvature and $\lambda_i = \lambda_f = \lambda$ (as implied by the figure), the free energy change ΔG° can be equated to the gap, ΔG_{if}° , between the minima of the two (constrained) free energy profiles [47] (a near equality is expected in general); the vertical energy gap (η_i) at the equilibrium configuration for the initial state (DBA) is equal to $\lambda + \Delta G^\circ$ [9]. Correspondingly, the final-state (D^+BA^-), gap, $-\eta_f$, is given by $\lambda - \Delta G^\circ$.

We note that the net diabatic free energy change,

$$G_{if}^\circ = G_f(\eta_f) - G_i(\eta_i) \quad (26)$$

is not in general identical to the quantity ΔG° based on the unconstrained free energies (Eq. 19), although the difference is expected to be minor (e.g., [36, 47]).

When $G_i(\eta)$ and $G_f(\eta)$ are taken to be parabolic, corresponding to linear coupling of the transferring electron to the rest of system with respect to progress along the reaction coordinate, considerable simplification is possible, leading in the classical (high temperature) limit to the familiar relationships of the Marcus theory [9], notably, the quadratic dependence of G_i^\ddagger on ΔG° (in the remainder of this chapter we ignore the distinction between ΔG° and ΔG_{if}°):

$$G_i^\ddagger = (\lambda + \Delta G^\circ)^2 / 4\lambda \quad (27)$$

where

$$\lambda = \lambda_i = \lambda_f \quad (28)$$

Enthalpic and entropic analogs of Eq. 27 are dealt with in [93], neglecting any temperature variation of λ (cf., [21]).

To be consistent with the condition noted following Eq. 23, the two parabolic profiles must have the same curvature, which can be represented by a harmonic force constant, k_η . Thus, we may write:

$$\lambda = k_\eta(\eta_i - \eta_f)^2/2 \quad (29)$$

When the reaction coordinate η corresponds to the solvent polarization mode, the dielectric continuum theory analog of Eq. 29 is:

$$\lambda = (1/\epsilon_{op} - 1/\epsilon_s) \int [D(\rho_f) - D(\rho_i)]^2 \quad (30)$$

where ϵ_{op} and ϵ_s are, respectively, the optical and static dielectric constants, and the displacement field D is a linear functional of the initial- (ρ_i) and final-state (ρ_f) charge density [9, 11a, 11b, 83, 89]. More detailed formulation and evaluation of λ is discussed in [94], with attention drawn to the indirect screening role of high-frequency (optical) modes in modifying the direct contributions of the lower-frequency (nuclear) modes.

While the use of effective energy surfaces defined in terms of free energies is commonplace in the electron transfer literature, we note an equivalent, alternative viewpoint, in which k_{et} is expressed in terms of probability distributions of the fluctuating potential-energy gap specified by η (as in Eqs. 20 and 21) [95].

1.3.3 TST Models

We now consider specific TST rate-constant models, taking explicit account of nuclear coordinates, Q , and wavefunctions, χ_n (see Section 1.3.1 of this chapter), so as to be able to include nuclear tunneling when necessary.

Golden rule

A convenient point of departure is provided by the golden-rule non-adiabatic rate-constant expression [8, 60] appropriate under the usual two-state approximation (TSA),

$$k_{et}^{TST} = (2\pi/\hbar)(T_{if})^2(FCWD), \quad (31)$$

where the “transfer integral” T_{if} is the *effective* electronic Hamiltonian matrix element coupling the initial (ψ_i) and final (ψ_f) states [17, 60], which differ, respectively, by having an electron localized primarily at D and A sites (see Figure 1). Comparative comments about different notations used to denote “D/A coupling elements” are deferred until Section 1.4.3 of this chapter.

The Franck–Condon-weighted density of states (FCWD) reflects the influence of all of the nuclear modes of the system, often represented in terms of effective normal

coordinates (Q_{r_i} and Q_{w_f} for the initial and final states, respectively) and associated quantum-mechanical Franck–Condon factors.

High-temperature classical limit

For sufficiently high temperature (where all nuclear frequencies ω obey the relation $\hbar\omega \ll k_B T$), FCWD takes on a limiting classical form,

$$\text{FCWD} = \exp(-G^\ddagger/k_B T)/(4\pi k_B T \lambda)^{1/2} \quad (32)$$

where G^\ddagger for the case of linear (harmonic) coupling to the medium is given by Eq. 27. It is important to distinguish G^\ddagger (Eq. 27), which may have appreciable entropic content, from the Arrhenius activation *energy* (or enthalpy) [36, 93]. Equation 32 may be reexpressed as

$$\text{FCWD} = \rho(0), \quad (33)$$

where $\rho(\eta)$ is the normalized classical density of initial states with respect to the gap η (i.e., $\rho(\eta) d\eta$ is the probability of finding the initial state in a configuration corresponding to a vertical gap in the range η to $\eta + d\eta$; see Figure 3); for linear coupling we have:

$$\rho(\eta) = \exp(-\{(\lambda + \Delta G^\circ - \eta)^2/4\lambda k_B T\})/(4\pi\lambda k_B T)^{1/2} \quad (34)$$

Thus, in the classical limit, the consequence of the energy-conserving golden-rule expression (Eq. 31) is simply to invoke the classical density of states at the transition state (i.e., the crossing, where $\eta = \eta^\ddagger = 0$, the point to which a radiationless electronic transition is confined due to the constraints of the Franck–Condon principle).

It has been noted [95] that λ in Eq. 34 plays two rather distinct roles: λ in the quadratic expression is a solvation energy which defines (with ΔG°) the vertical gap at equilibrium, whereas the other λ 's control the width of the Gaussian distribution characteristic of the linear coupling model.

The FCWD expressions for thermal ET (e.g., Eq. 32 or its low-temperature quantal counterpart) may be adjusted to accommodate optical electron transfer if ΔG° is replaced with $\Delta G^\circ + \hbar\nu$ (emission) or $\Delta G^\circ - \hbar\nu$ (absorption), where $\hbar\nu$ is the optical transition energy [96]. The relationship between thermal and optical coupling elements is discussed in Section 1.4.2 of this chapter.

Quantal effects

At lower temperatures, where quantal effects become appreciable for the high-frequency modes, Eq. 31 may be recast as a superposition of vibronic state-to-state processes [14],

$$k_{\text{et}}^{\text{TST}} = (2\pi/\hbar) \sum_{r_i w_f} (P_{r_i})(T_{r_i w_f})^2 (\text{FCWD}')_{r_i w_f} \quad (35)$$

where P_{r_i} is the normalized distribution of initial vibronic states (typically in terms

of Boltzmann factors), where the vibronic coupling factor $(T_{v,w_f})^2$ is given by

$$(T_{v,w_f})^2 = (T_{if})^2 (S_{v,w_f})^2, \quad (36)$$

and $(S_{v,w_f})^2$ is a vibrational Franck–Condon factor (i.e., the square of the corresponding vibrational overlap integral). The implicit relationship between the quantities $(\text{FCWD}')_{v,w_f}$ and FCWD, as obtained from comparison of Eqs. 31, 35, and 36, is given by

$$\text{FCWD} = \sum_{v,w_f} P_{v_i} (S_{v,w_f})^2 (\text{FCWD}')_{v,w_f} \quad (37)$$

The nuclear tunneling implicit in the Franck–Condon factors is of particular importance in the inverted region ($-\Delta G^\circ > \lambda$). In such cases, the effective barrier is greatly reduced as a result of nuclear tunneling [14], in comparison with the classical barrier, which according to Eq. 27 would rise monotonically with increasing exothermicity in the inverted region.

Condon approximation

In Eqs. 31, 36, and 37 we have employed the Condon approximation [66], factoring T_{if} out of the full vibronic matrix element, with the understanding that T_{if} is to be evaluated for values of the nuclear coordinates pertinent to the configuration or range of configurations of the system in which the ET process occurs. The validity of the Condon factorization depends on the extent to which T_{if} varies with the coordinates Q , a topic to which we return below. The coordinates of interest in this connection include the reaction coordinate (η in Figure 3), as well as others such as conformational modes of the DBA system. The influence of fluctuations in these coordinates (and hence in the magnitude of T_{if}) on the overall kinetics depends in detail on the relationship between the timescale for such fluctuations and the timescales of the other dynamic processes [97].

The use of the Condon approximation [66] leads to electronic symmetry control, dictating vanishing rate constants when ψ_i and ψ_f belong to different irreducible representations of a given point group. In such cases, vibronic coupling (e.g., involving $\partial T_{if}/\partial Q_{v_i}$, etc.) may actually lead to rate constants of substantial magnitude [71]. On the other hand, in other related cases, symmetry control appears to be operative, as expected on a purely electronic basis [90].

Techniques for treating quantized nuclear motion

It is desirable to bridge the gap between the general quantal expression for k_{et} given by Eqs. 35–37 with its explicit summation of vibronic contributions and the simplicity of the classical, harmonic model displayed in Eqs. 33 and 34. As one device for achieving this goal, we switch perspectives from the constrained diabatic free energies, $G_i(\eta)$ and $G_f(\eta)$, as in Eq. 22, to an auxiliary (unconstrained) free-energy function, $G(\tau)$, based on the “hybrid” partition function $Z(\tau)$ [36, 98] (cf., Eq. 18):

$$Z(\tau) = \int d\{Q\} \exp[-(1-\tau)H_i/k_B T] \exp(-\tau H_f/k_B T) \quad (38)$$

$$G(\tau) = -(k_B T) \ln Z(\tau) \quad (39)$$

where, in general, H_i and H_f are quantum-mechanical Hamiltonians.

The continuous variable τ , which may be thought of as a “charging parameter” spanning the reactant ($\tau = 0$) and product ($\tau = 1$) limits, corresponds closely to the parameter m introduced originally by Marcus [11a] and may be employed as the reaction coordinate [36, 98] (an alternative to η). Strictly speaking, τ is a dimensionless quantity referring to a point on the imaginary time axis (t), arising in conjunction with analytic continuation of the Fourier representation of the Dirac delta function in the fundamental statement of the golden rule [36, 99]:

$$\tau = it/(\hbar/k_B T) \quad (40)$$

Solution of the golden-rule expression for the non-adiabatic ET rate constant by applying the saddle-point (or stationary phase) approximation yields [36],

$$k_{\text{ct}} = (2\pi/\hbar)(T_{if})^2 \exp(-G^\ddagger/k_B T) / \{4\pi k_B T [-(1/2)d^2 G(\tau)/d\tau^2|_{\tau^\ddagger}]\}^{1/2} \quad (41)$$

where τ^\ddagger is defined by the condition

$$dG/d\tau|_{\tau^\ddagger} = 0 \quad (42)$$

and where the activation free energy G^\ddagger is given by

$$G^\ddagger = G(\tau^\ddagger) - G(0) \quad (43)$$

In contrast to the delta-function constraint of Eq. 22, where the transition state corresponds to $\eta = \eta^\ddagger = 0$, the transition state represented by Eqs. 42 and 43 occurs at the τ value for which the mean value of ΔV_{if} (Eq. 21) is zero [36]:

$$\left(\int d\{Q\} \rho(\tau^\ddagger) \Delta V_{if} \right) / Z(\tau^\ddagger) = 0 \quad (44)$$

where the hybrid density operator $\rho(\tau^\ddagger)$ is the integrand of Eq. 38 when $\tau = \tau^\ddagger$.

In the case of a two-state system linearly coupled to a harmonic oscillator bath (the spin-boson model), Eq. 41 for a thermoneutral process ($\Delta G^\circ = 0$), where $\tau^\ddagger = 1/2$ [99], may be reexpressed compactly in the following semiclassical form [18, 94, 99a]:

$$k_{\text{ct}} = (2\pi/\hbar)(T_{if})^2 \left(\exp \left\{ - \sum_j (\lambda_j/4k_B T) [\tanh(u_j/4)/(u_j/4)] \right\} \right) / \left((4\pi k_B T) \sum_j \{ \lambda_j (u_j/2) [\text{csch}(u_j/2)] \} \right)^{1/2} \quad (45)$$

where $u_j \equiv \hbar\omega_j/k_B T$, ω_j is the frequency of the j -th harmonic mode, and λ_j is the additive contribution of the j -th mode to λ (for arbitrary ΔG° , τ^\ddagger must be determined numerically, except in the case of a single mode [99a]). In the high-temperature classical limit ($\hbar\omega_j \ll k_B T$), Eqs. 31–34 are recovered. In this case, one may identify the quantity $-(1/2)d^2G|d\tau^2|_{\tau^\ddagger}$ with λ , and $G(\tau)$ is given by [36, 98],

$$G(\tau) = (\Delta G^\circ + \lambda)\tau - \lambda\tau^2 \quad (46)$$

From Eq. 46 it is easily seen that $\tau^\ddagger = (\Delta G^\circ + \lambda)/2\lambda$, yielding the classical result for G^\ddagger (Eq. 27). In general, the argument of the exponential in Eq. 45 gives an explicit expression for reduction of the activation barrier due to nuclear tunnelling [36, 94, 99]. The influence of nuclear tunneling at finite temperatures on the magnitude of the prefactor (second line of Eq. 45) is typically minor [26, 160].

The techniques of discretized Feynman path integrals make the use of Eq. 41 practical for the more general case of quantized nuclear motion which is not restricted to harmonic behavior [36, 94, 99b]. Applications of this approach are discussed in Section 1.5 of this chapter.

Mixed quantal–classical treatment

At temperatures where quantal effects may be significant only for a well-defined subset of nuclear modes, a hybrid quantal–classical variant of Eqs. 35–37 may be employed, if separable quantal and classical modes are assumed, in which the summation in Eq. 35 is restricted to the quantized manifold of nuclear states. If the classical modes are assumed to be harmonic, then the modified (FCWD) $_{v_i w_f}$ is given by [14, 100]:

$$(\text{FCWD})_{v_i w_f} = \exp(-G_{v_i w_f}^\ddagger/k_B T)/(4\pi\lambda_{\text{cl}}k_B T)^{1/2} \quad (47)$$

where

$$G_{v_i w_f}^\ddagger = (\Delta G^\circ + \Delta E_{v_i w_f} + \lambda_{\text{cl}})^2/4\lambda_{\text{cl}} \quad (48)$$

and where $\Delta E_{v_i w_f}$ is the energy change in the quantal manifold. In this approach, the single collective reaction coordinate η for *all* nuclear modes (as in Section 1.3.2) is replaced by a collective *classical* reaction coordinate, and the total rate constant is based on a superposition of quantal state-to-state processes, each governed by the *classical* reorganization free energy (λ_{cl}) and the appropriate effective net free-energy charge (see Eq. 48),

$$\Delta G_{v_i w_f}^\circ = \Delta G^\circ + \Delta E_{v_i w_f} \quad (49)$$

If the quantized nuclear motion is represented by a set of (harmonic) normal coordinates common to both initial and final diabatic states, then $\Delta E_{v_i w_f}$ is given by:

$$\Delta E_{v_i w_f} = \sum_j (\Delta n_j)_{v_i w_f} (\hbar\omega_j) \quad (50)$$

where $(\Delta n_j)_{v_i w_j}$ is the change in quantum number of mode j in the $v_i \rightarrow w_j$ transition and ω_j is the frequency. For harmonic modes, explicit expressions for the Franck-Condon factors $[(S_{v_i w_j})^2]$ are available [100]. For the often-used model based on a single mode initially in its ground-state, FCWD (Eq. 37) is given by [14, 100]:

$$\begin{aligned} \text{FCWD} = & (4\pi\lambda_{\text{cl}}k_{\text{B}}T)^{-1/2} \sum_{w=0}^{\infty} [\exp(-S)](S^w/w!) \\ & \times \exp[-(\lambda_{\text{cl}} + \Delta G^\circ + w\hbar\omega)^2/4\lambda_{\text{cl}}k_{\text{B}}T] \end{aligned} \quad (51)$$

where $S = \lambda_r/\hbar\omega$ and λ_r and ω are, respectively, the reorganization energy and the harmonic frequency associated with the quantized mode. Equation 51 may be straightforwardly generalized to include more than one quantized harmonic mode [100].

The partitioning of the nuclear manifolds outlined above may be formally treated in terms of a convolution integral of a product of “lineshape” functions for the quantal and classical manifolds, allowing energy interchange between the manifolds, subject to overall energy conservation [101]. Analogous convolution-based treatments have been applied to energy-transfer kinetics [102], where the partitioning is between manifolds of the donor and acceptor sites. Such a partitioning in the case of ET has been shown to be invalid in cases where λ involves coherent coupling of D and A sites [101b].

Departure from the non-adiabatic limit

The non-adiabatic expressions for $k_{\text{et}}^{\text{TST}}$ (Eqs. 31 and 35) will be valid provided that the rate-determining step is resonant “electron tunnelling” [89] (whose probability is controlled by T_{if}), in contrast to possible alternative dynamic bottlenecks associated with the various nuclear degrees of freedom [13, 14, 35, 84]. (Examples of adiabatic electron transfer in organic mixed-valence systems are discussed in [161].) Within the TST regime at high temperature, the Landau–Zener (LZ) model [103] in the case of a harmonic system shows that the non-adiabatic (golden rule) limit is valid when the following inequality is obeyed [8, 9]:

$$\kappa_{\text{cl}} = (T_{if})^2(\pi^{3/2})/(\hbar\omega_{\text{eff}})(k_{\text{B}}T\lambda)^{1/2} \ll 1 \quad (52)$$

where κ_{cl} is the electronic transmission factor (independent of ΔG° , at the level adopted here), and ω_{eff} is the effective frequency associated with vibrational motion along the reaction coordinate. The expression for κ_{cl} in Eq. 52 is based on the assumption of inertial (ballistic) motion of the system through the crossing region (cf. [104]). Equation 52, which in effect implies that the effective frequency of the transferring electron is small compared with that associated with the reaction coordinate η in Figure 3, is a statement of the breakdown of the validity of the BOA (hence the designation “non-adiabatic”) [8, 9b]. However, as noted in Section 1.3.1, the use of a diabatic basis (which varies slowly with Q_{v_i} and Q_{w_j}) usually permits the

Figure 4. Schematic depiction of the limits of (a) weak (non-adiabatic) and (b) strong (adiabatic) coupling. The dashed and solid lines refer to diabatic and adiabatic surfaces, respectively. The vertical bars denote the “reaction zone” in which D and A sites are close to resonance [105].

neglect of non-Born–Oppenheimer coupling elements [8], thus yielding a model cast in terms of purely electronic (T_{if}) and vibrational [$(S_{r,w_i})^2$] matrix elements.

As the strength of D/A coupling increases, governed by T_{if} , a number of adjustments to the TST rate constant formulation may be required. If nuclear quantum effects are minor, the LZ model may be applied to cases of arbitrary T_{if} magnitude, expressed either in terms of a diabatic or adiabatic basis [8]. The relative merits of the two bases (as well as limitations in the applicability of the LZ model) have been discussed recently in conjunction with the analysis of electron transfer from strongly-coupled D/A initial states prepared optically [39, 65].

The coupling strength also affects the activation free energy. The simple expression for G^\ddagger in Eq. 27 based on the harmonic weak-coupling (small T_{if}) limit must be modified to reflect the consequences of avoided crossing on the height and shape of the barrier [9, 84c]. This effect is depicted schematically in Figure 4, showing as examples the non-adiabatic (weak D/A coupling) limit ($\kappa_{el} \ll 1$) with a cusp-like adiabatic barrier (Figure 4a), and the situation of stronger D/A coupling ($\kappa_{el} \lesssim 1$), which results in a rounded adiabatic barrier (Figure 4b). The “width” of the region along the reaction coordinate for which quasi-resonant ET is appreciable (in the sense of the half-width at half-height of the function $\langle \psi_2 | d/d\eta | \psi_1 \rangle$) is given [105] by $|\eta| \sim 2|T_{if}|$. At a more fundamental level, the magnitude of T_{if} influences G^\ddagger

indirectly by defining the effective timescale of the transferring electron compared with the timescale of the electronic response of the medium [16].

The double-well form of the lower-energy adiabatic energy profile at the level of the TSA (as in Figure 4), pertains to systems in the normal regime and with $2|T_{if}| \leq \lambda$.

Beyond the TSA

While the two-state approximation (TSA) introduced in Section 1.3.1 accounts well for many classes of electron-transfer kinetics, there are, of course, situations in which a high density of electronic states in the initial- and final-state manifolds makes it necessary to generalize the TSA expressions given, for example, by Eqs. 31–37. A paramount example is the case of metal or semiconductor electrodes, where one must deal essentially with an electronic continuum [25, 31, 32, 106]. In spite of this complication, one may still obtain k_{et} expressions with similar form to those shown above when reaction “exothermicity” is small (i.e., the difference between the electrode Fermi level and the standard potential of the redox species is small compared to λ) [25b]. Nevertheless, in the “inverted region”, k_{et} at electrodes is generally observed to approach a constant maximum value with increasing driving force (for an exception, see [107]), in contrast to the fall-off predicted in the case of the TSA (see Eq. 27).

A number of other situations may require a modest extension of the TSA; for example, 1) Multiple initial and final diabatic states involved in coupled electron/proton transfer [20]; 2) Cases of D/A systems undergoing photoinitiated charge-separation (CS) and charge-recombination (CR) processes (Figure 2b), where state mixing makes a combined three-state treatment preferable [71b,c] to separate two-state treatments; and 3) Cases involving the presence of low-lying intermediate states, such as those associated with the intervening bridge (e.g., [86]). When dealing with electronic coupling in the context of extended state manifolds of this type, one must also consider the possible importance of vibronic features [71b].

1.3.4 Role of Solvent Dynamics

It is of considerable interest to examine the extent to which solvent (or other medium) modes may lead to dynamical bottlenecks requiring a departure from the TST framework [35]. This effect can be represented by a transmission factor, κ [84, 87], where

$$k_{\text{et}} = \kappa k_{\text{et}}^{\text{TST}} \quad (53)$$

where $k_{\text{et}}^{\text{TST}}$, in turn, may be expressed as

$$k_{\text{et}}^{\text{TST}} = \kappa_{\text{cl}} k_{\text{et}}^{\text{AD}} \quad (54)$$

with κ_{cl} (Eq. 52) spanning the range from non-adiabatic ($\ll 1$) to weakly adiabatic (≤ 1) and strongly adiabatic ($\kappa_{\text{cl}} = 1$), denoted below, respectively, as NA, WA, and

SA (see Figure 4). In Eq. 54, $k_{\text{ct}}^{\text{AD}}$ is the TST expression $(\omega_{\text{eff}}/2\pi) \exp(-G^\ddagger/k_{\text{B}}T)$, where ω_{eff} was introduced in Eq. 52.

Classical solvent models

Early treatments focused on a classical overdamped solvent model (zero-frequency friction) [13b, 14]. In the NA and WA cases, where initial- and final-state wells are sharply defined, separated by a narrow cusp-like barrier, one may adopt a steady-state model of the type displayed in Eq. 7,

$$k_{\text{ct}} = (ac_f)/(b + 2c_f) \quad (55)$$

where, for simplicity, we treat the case of a symmetric ET process, where $b = b'$.

Taking k^{TST} as given by Eq. 4, we thus have:

$$\kappa = (c_f/c)/(1 + 2c_f/b) \quad (56)$$

Here we allow for the possibility of diffusion control in the barrier-crossing process (c_f) in contrast to the inertial rate constant (c) generally assumed for passage from activated reactants to products in the TST model [84, 87]. The activation (a) or deactivation (b) rate constants may also be diffusive. The occurrence of $\kappa < 1$ reflects diffusive recrossings of the system in the TS region. In the absence of diffusional bottlenecks ($c_f = c \ll b$), κ becomes unity (i.e., the TST limit).

The activation rate constant a controlling diffusion within the wells is expressed by the following equation [84]:

$$a = k_D = (1/\tau_L^{\text{eff}})(\Delta G^\ddagger/\pi k_{\text{B}}T)^{1/2} \phi \exp(-G^\ddagger/k_{\text{B}}T), \quad (57)$$

where τ_L^{eff} is an effective longitudinal relaxation time, the correction factor ϕ may be taken as unity for $\Delta G^\ddagger/k_{\text{B}}T \geq 5$, and $a/b = \exp(-G^\ddagger/k_{\text{B}}T)$. Solvent dielectric relaxation also controls the barrier-crossing dynamics (c_f) and may be modeled using Grote–Hynes theory [108], which is not limited to overdamped solvent response.

While significant departures of κ from unity might be expected in the WA or SA case if τ_L^{eff} is taken as the conventional longitudinal relaxation time, τ_L (or some suitable mean value for non-Debye solvents), corresponding to zero-frequency friction, it has been shown from formal analysis and computer simulation [84] that taking proper account of the relevant higher-frequency components of the friction leads to substantially smaller departures of κ from unity (i.e., a reduced importance of barrier recrossing). Furthermore, even when the barrier is quite cusp-like, the most important manifestation of solvent dynamics is found in the barrier region (c_f), as opposed to within the wells (k_D). In the SA limit, when the diabatic cusp becomes sufficiently rounded (as characterized by imaginary frequency ω_b associated with the barrier curvature at the TS), one reaches the situation where the zero-frequency friction, ζ_L , is dominant, and we obtain the Smoluchowski result [84]:

$$\kappa = \omega_b/\zeta_L \quad (58)$$

where ζ_L is related to τ_L by the inertial solvent frequency (ω_L),

$$\zeta_L = \omega_L^2 \tau_L \quad (59)$$

In the limit of Eq. 58, we have $c_f = (\omega_b/\omega_L)/\tau_L$, where the rate constant c in k^{TST} (Eq. 4) is equated to ω_L .

Inclusion of molecular modes

Current views of solvent dynamics recognize the importance of a complex interplay among solvent and molecular modes, which involves a variety of timescales [35]. In contrast to the simple solvent-only models, which implicitly confine the reactive transition to a “pinhole sink” at the TS, where $\eta = 0$, some recent models “dilute” the influence of solvent dynamics by introducing a classical (and rapidly relaxing) low-frequency molecular mode, which serves to provide a reactive sink of finite width with respect to a diffusive solvent mode [13a, 24]. Inclusion of quantal, high-frequency modes is, of course, necessary for proper account of nuclear tunneling [14, 24] (see Section 1.3.3), although these modes by themselves do not relax the pinhole constraint [35]. Some essential features of the new models are represented by the following generic form for the effective activation free energy,

$$G_{\text{eff}}^\ddagger = (\Delta G_{\text{eff}}^\circ + \lambda_{\text{cl}}')^2 / 4\lambda_{\text{cl}}' \quad (60)$$

where λ_{cl}' is a classical reorganization energy. It should be noted that Eq. 60 neglects any contribution to G^\ddagger arising from temperature-dependence of medium relaxation times (e.g., τ_L^{eff} in Eq. 57).

In the Bixon–Jortner (BJ) model [14a], a steady-state form of the type given in Eq. 3 is employed for k_{ct} , where $k_{\text{ct}}^{\text{TST}} = (a/b)c$ is the single-mode quantal non-adiabatic TST expression given by Eqs. 31 and 51, with $\lambda_{\text{cl}}' = \lambda_s$ (the solvent reorganization energy) and $\Delta G_{\text{eff}}^\circ$ given by Eq. 49, and where a is given by the zero-frequency diffusion expression, Eq. 57, with $a/b = \exp(-\Delta G^\circ/k_B T)$.

In the Sumi–Marcus (SM) model [13a], the perspective is changed, with a TST rate constant k_m^{TST} based on a low-frequency molecular mode (m) as the reaction coordinate, and with G^\ddagger dependent on a diffusive solvent coordinate X . For ease of comparison with other models, we transform X (relative to its definition in [13a]) so as to correspond to a continuous charging parameter ($X = 0$ for the bottom of the reactant well, and $X = 1$ for the bottom of the product well; for the case of parabolic free energy profiles the transformation is linear; the more general situation is dealt with in [98]). Also, $\lambda_{\text{cl}} = \lambda_s + \lambda_m$ and $\lambda_{\text{cl}}' = \lambda_m$, where λ_m is the reorganization energy associated with the low-frequency mode m . These definitions lead to the following equation:

$$\Delta G_{\text{eff}}^\circ(X) = \Delta G^\circ + (1 - 2X)\lambda_s \quad (61)$$

and $G_{\text{eff}}^\ddagger(X)$ in Eq. 60 is defined accordingly. The larger $\lambda_m/\lambda_{\text{cl}}'$ is, the broader the distribution available in the solvent coordinate for reaction $[(k_B T \lambda_m / 2\lambda_s^2)^{1/2}]$ is, as

governed by the X -dependent k_m^{TST} [13a]. In the BJ model, which does not include low-frequency molecular modes, one effectively has $\lambda_m = 0$ (i.e., the pinhole sink limit). It should be noted that the width of the “reactive sink” with respect to the solvent coordinate discussed here is quite distinct from the effective “width” for resonant ET introduced at the end of Section 1.3.3 (see also Figure 4).

Barbara and coworkers [24] combined the flexibility of the finite-sink SM approach with the quantal features of the BJ model; this yielded a hybrid model defined once again by $\lambda_{\text{cl}}' = \lambda_m$, but with $\Delta G_{\text{eff}}^\circ$ given by

$$\Delta G_{\text{eff}}^\circ(X) = \Delta G^\circ + \Delta E_{\text{icfr}} + (1 - 2X)\lambda_s \quad (62)$$

(cf., Eqs. 49 and 50).

In addition to the crucial role of molecular modes, both low and high frequency, Bagchi has also emphasized the further need to consider the role of ultrafast (underdamped) solvent response [35] (see also Section 1.3.4 and [84]).

Aside from the energetics and dynamics of solvent reorganization, the roles of dissolved electrolyte on ET processes carried out in solution with finite ionic strengths have been the subject of recent experimental [56] and theoretical [57] study. The various analyses suggest that continuum-based treatments or Debye–Hückel descriptions of ionic atmospheres are inadequate and point to the importance of specific ion-pairing effects, including dynamic as well as energetic factors.

1.4 Coupling Elements

1.4.1 Basic Properties

Theoretical and computational electronic structure techniques have led to major progress in the elucidation of the detailed basis of long-range coupling between D and A sites. There now is a theoretical framework [6, 17, 30, 34, 38, 61–64, 70, 89] which permits the calculation of coupling elements (T_{if}) for complex ET systems in generally good accord with available estimates based on experimental data (e.g., see reviews in [1] and [3]). The calculated coupling elements may be analyzed in terms of local chemical units, which allow the overall magnitude to be represented as a superposition of a number of competing “pathways” (e.g., [34, 60–64, 109–114]), thus making possible an assessment of the relative importance of the various pathways in achieving the overall coupling, although due account must be taken of cancellation due to destructive interference [27, 60, 63]. The information obtained from such analyses helps to provide a rational basis for synthesizing coupling elements for families of DBA systems, where transferable quantities defined in terms of the chosen local units are used (e.g., see [63], [70], and [111]).

The ideas so fruitful in dealing with the coupling that controls ET are increasingly finding useful application where related energy transfer [26, 76] and magnetic exchange [77–79] phenomena are analyzed; the power of superexchange models (dealt with in detail in Section 1.4.3) is, in particular, exploited for providing a

unified account of diverse D/A interactions. In this section, we highlight a number of theoretical features of importance in formulating expressions for T_{if} .

In the case of thermal ET, which applies either to ground state ET or photo-initiated ET from a vibrationally relaxed excited state (cf., [15d]), we now define the effective coupling T_{if} by employing the two-state approximation (TSA) introduced in Eqs. 14–15:

$$T_{if} = (E_1 - E_2)/2 = (\langle \psi_1 | H^{\text{el}} | \psi_1 \rangle - \langle \psi_2 | H^{\text{el}} | \psi_2 \rangle)/2 \quad (63)$$

where $E_1(E_2)$ is the eigenvalue associated with $\psi_1(\psi_2)$ in the transition state (TS). The diabatic energy matching at the TS (Eq. 15) then implies (via Eq. 14, where we have 50:50 mixing or $\cos \theta = \sin \theta = 1/\sqrt{2}$):

$$T_{if} = \langle \psi_i | H^{\text{el}} | \psi_f \rangle, \quad (64)$$

thus demonstrating that T_{if} may be expressed either in terms of adiabatic or diabatic quantities. The sign of T_{if} is a physical observable, but is contingent on the phase conventions entailed in the definitions of ψ_i and ψ_f (and hence via Eq. 14, also ψ_1 and ψ_2) [6, 34, 60].

Many-particle framework

In a process of the type (see Figure 1) described below:

a single electron is nominally transferred from D to A (analogous processes involving multiple-electron transfer are also possible; see the chapter by Skourtis and Beratan). Does this mean that T_{if} can be viewed as a simple one-electron matrix element or resonance integral? Analysis of D/A coupling, based on a detailed examination of the electronic manifolds of B, however, suggests that, in general, the process described by Eq. 65 is more properly viewed as a superposition of a number of one-particle charge-transfer processes (“pathways”) occurring in parallel, including transfer of an electron in one direction and transfer of a “hole” in the opposite direction, as well as more complex processes involving both electrons and holes [6, 34, 60, 109, 111, 113–115]. While the issue of electron *vs* hole transfer in this context constitutes a physical (not semantic) distinction, one must be careful, because the precise details depend on the basis employed for the analysis of the electronic manifolds of the DBA system. Superimposed on the net transfer of charge between D and A, one may also expect local response (i.e., polarization relaxation) of the system to the oxidation and reduction occurring, respectively, at D and A [6, 60, 114]. We note that “system” in this connection may be broadly understood to include the “solvent” as well as the DBA “solute”.

With the foregoing multiparticle perspective in mind, it is of interest to combine analysis and calculation to determine the extent to which T_{if} , strictly speaking a many-electron quantity, may be cast as an effective one-particle (i.e., orbital) matrix element, T_{DA} , where DA in this context denotes the “donor” and “acceptor” orbi-

tals, confined primarily to the D and A sites, respectively. In particular, it has been found in a number of cases [6, 60, 114] that the many-electron (relaxation) effects may be captured by electronic Franck–Condon-type overlap integrals, S_{if}^{el} , with magnitude ≥ 0.9 :

$$T_{if} = S_{if}^{\text{el}} T_{\text{DA}} \quad (66)$$

where T_{DA} may be viewed as the matrix element of an effective one-particle Hamiltonian (e.g., [114]), and S_{if}^{el} represents the influence of an effective background many-electron core (in addition to “solute,” i.e., DBA, contributions to S_{if}^{el} , similar effects due to solvent have been reported [16b]). The *electronic* S_{if}^{el} factor is of course quite distinct from the *vibrational* overlap integrals ($S_{v_i v_f}$, as in Eq. 36) which may be used to “dress” the electronic factor (T_{if}) [14].

The estimates for S_{if}^{el} cited above were all for thermal ground-state systems, based on self-consistent field (SCF) wavefunctions. Studies with more elaborate wavefunction models have provided examples where electron-correlation effects (relative to the mean-field SCF level) make appreciable contributions to T_{if} magnitudes (e.g., [110, 116]). Furthermore, for the important case of excited state ET processes, where the SCF approach is not generally applicable, the viability of a one-particle model for T_{if} becomes less clear.

Multistate framework and spin-state dependence of T_{if}

While a single-matrix element, T_{if} , suffices for the simple TSA, an extended treatment may be required in cases of degenerate or quasi-degenerate initial and final states associated with open-shell reactants and/or products, since the ET process may then involve a distribution of thermally populated initial states and several possible final states. Even in such a multistate framework, it may be possible to cast the overall rate constants as a superposition of individual processes, each treated at the level of the TSA.

Cases of near-degeneracy due to both space and spin have been dealt with in the literature (e.g., see [117]). Here we consider specifically the case of spin [77]. In the simplest case, an ET process involves a single electron transferring between D and A cores, each of which has a singlet spin state ($S_{\text{D}} = S_{\text{A}} = 0$). In the general case where each core has a non-zero spin, the system involves both electron transfer and magnetic exchange (“double exchange”) and T_{if} becomes spin-state dependent [77, 79]. For example, when each core has spin S_{c} and the transferring electron is high-spin coupled to S_{c} at the site where it is resident (D or A), the dependence of T_{if} on the overall spin of the system, S , may be expressed by the following equation [77a]:

$$T_{if}(S_{\text{c}}, S) = T_{if} f(S_{\text{c}}, S) \quad (67a)$$

where

$$f(S_{\text{c}}, S) \propto [(2S + 1)^2 / 2(2S_{\text{c}} + 1)(2S_{\text{c}} + 2)]^{1/2} \quad (67b)$$

Thus, the electronic transmission factor κ_{el} (Eq. 52) will increase monotonically

with the overall spin (S) for a given S_c , creating the possibility that one may pass from the non-adiabatic to the adiabatic regime in the course of spanning the range of S values ($1/2$ to $2S_c + 1/2$). In weighting the contribution of spin state S to k_{et} for a thermal process (proportional to $[T_{if}(S_c, S)]^2$ in the non-adiabatic limit), one must also include the spin degeneracy factor, $2S + 1$, as well as a Boltzmann factor (based, for example, on a Heisenberg magnetic exchange model for relative spin-state energies, or a more elaborate model if electronic delocalization is appreciable) [77a]. If there are spatially degenerate (or quasi-degenerate) D or A orbitals, then one must also consider orientation-dependence of the spatial factor (T_{if} in Eq. 67a) with respect to different members of the degenerate set. As a practical device, one may employ an orientationally averaged T_{if} value (in the root-mean-square sense) [117]. Spin-orbit coupling provides another mechanism for spin-control of T_{if} magnitude. In its absence, a finite T_{if} value requires overall spin conservation. Even when such conservation is maintained, spin-orbit coupling may be crucial, as in the case of $[\text{Co}(\text{NH}_3)_6]^{2+/3+}$ self-exchange, involving primarily low-spin (singlet) Co^{3+} and high-spin quartet Co^{2+} [117]. Despite the fact that this process is formally spin-allowed, without a modest spin-orbit mixing of the low-spin (doublet) with the high-spin Co^{2+} state, the coupling would be very weak, corresponding to a “three-electron” process (involving intra-site electronic reorganization as well as inter-site electron exchange) [117]. See also Ref. [36].

A final comment pertains to the continuous electronic manifolds in the case of electron transfer at electrodes. Here one may formulate T_{if} to depend explicitly on the states within the accessible portion of the electrode band structure [31]. Alternatively, one may employ a mean value (e.g., based on the Fermi level) [25b, 32b, 106].

Nonorthogonality

The preceding discussion has been based on the assumption of orthonormal electronic states (see Eq. 14). In some cases it is advantageous to employ a non-orthogonal diabatic basis, especially when T_{if} is evaluated directly in terms of variationally determined charge-localized SCF [34] (or, in some cases, correlated [116a]) wavefunctions, which are generally nonorthogonal:

$$S_{if} = \int \psi_f \psi_i \neq 0 \quad (68)$$

where S_{if} is the total electronic overlap integral, in contrast to the electronic Franck-Condon factor S_{if}^{el} (Eq. 66), which pertains only to the “core” of spectator electrons. We now have the following equation:

$$T_{if} = (H_{if} - S_{if}\bar{H})/(1 - S_{if}^2) \quad (69)$$

where, for thermal electron transfer (resonant D and A sites) [6, 60],

$$\bar{H} = H_{ii} = H_{ff} \quad (70)$$

$$H_{if} = \langle \psi_i | H^{\text{el}} | \psi_f \rangle \quad (71)$$

(Eq. 64 corresponds to the special case where $S_{if} = 0$).

We also note that Eq. 69 may be generalized to accommodate the nonresonant situation ($H_{ii} \neq H_{jj}$) [6, 60]:

$$T_{if} = (H_{if} - S_{if} H_{jj}) / (1 - S_{if}^2) \quad (72)$$

$$T_{ji} = (H_{ji} - S_{ji} H_{ii}) / (1 - S_{ji}^2) \quad (73)$$

The apparent non-Hermitian relationship (i.e., $T_{if} \neq T_{ji}$, even though $H_{if} = H_{ji}$ and $S_{if} = S_{ji}$), is an artifact of the Condon factorization of the full vibronic matrix element, and, in a complete vibronic model, the vibrational manifold would compensate the mismatch in H_{ii} and H_{jj} [6, 60]. In using the Condon-factorized form (Eqs. 72 and 73), one may simply bypass the problem by using a mean value (\bar{H}) for H_{ii} and H_{jj} , thereby reverting to the Hermitian form of Eq. 69.

Influence of medium on T_{if}

There are a number of ways in which the medium might be expected to influence T_{if} magnitudes (over and above the modest many-electron Franck–Condon effect noted above). By medium we refer to the environment of the DBA complex (Figure 1). Typically, it will be a polar solvent. Solvent molecules may, of course, constitute part of the “bridge” (e.g., in the case of solvent-separated ion pairs [118]), which does not necessarily consist of a complete sequence of covalent linkages between D and A [34, 60, 89, 110, 111].

A polar medium may affect T_{if} as a result of its electrostatic field, either long-range (as representable by a continuum or molecular-level model) or short-range (e.g., by specific hydrogen-bonding). The field (which varies with fluctuations of the medium) can modulate the tails of the D and A orbitals, either directly by controlling the degree of radial localization of the orbitals, or indirectly by modifying the energy gaps which control superexchange coupling (Section 1.4.3). In practice, such effects may be quite small [119]. In addition to these electrostatic effects, the electronic manifold of the medium in the immediate vicinity of the primary bridge may provide superexchange pathways, which substantially affect the overall magnitude of T_{if} , thus, in effect, serving to expand the size of the bridge. The operational choice of the “bridge” is guided by the objective of including all sites for which direct orbital participation has an appreciable effect on T_{if} [89, 90]. In some cases, of course, local D and A groups may be defined as being in contact (as in contact ion pairs), thus eliminating the need for a “bridge” altogether.

1.4.2 Comparison of Thermal and Optical Processes

The Mulliken–Hush model

Important connections between optical and thermal ET may be established if the matrix elements of the dipole moment operator (μ) as well as the Hamiltonian are used [12, 30]. In particular, we note two expressions defined within the above TSA; the first of these is given by Eq. 74:

$$T_{if} = |\bar{\mu}_{12}| \Delta E_{12} / |\Delta \mu_{if}| \quad (74)$$

where

$$\mu_{k\ell} = \langle k | \hat{\mu} | \ell \rangle \equiv \int \psi_k \hat{\mu} \psi_\ell \quad (75)$$

$$\Delta \mu_{k\ell} \equiv \mu_{\ell\ell} - \mu_{kk} \quad (76)$$

$$\Delta E_{12} \equiv E_2 - E_1 \quad (77)$$

The second expression is given by Eq. 78:

$$\Delta \mu_{12} = \Delta q \Delta \mu_{if} \quad (78)$$

where

$$\Delta q = 1 - 2(\sin \theta)^2 \quad (79)$$

Here, Δq is the fraction of an electronic charge transferred within the TSA (see Eq. 14). In Eqs. 74–79, we have adopted the common assumption [12] that the inter-site diabatic dipole matrix element μ_{if} is negligibly small. With this assumption, it also follows that $\Delta \mu_{12}$, μ_{12} , and $\Delta \mu_{if}$ are collinear. Of course, if $\mu_{if} \neq 0$ in actual practice, this collinear situation will not be maintained. In such a case, one may adopt a reference direction (e.g., as defined by $\Delta \mu_{12}$), and then use the projections of the other dipole matrix elements along this direction [30]. We note that practical use of Eq. 74 requires some estimate of $\Delta \mu_{if}$, a measure of the effective separation of the D and A sites. We also note that the preceding equations are exact within the stated assumptions and do not depend on the use of perturbation theory [120]. A final caveat about the charge-transfer direction: in the limiting case of symmetry-equivalent D/A sites corresponding to a C_n point group (as might pertain to a TS structure), there is no charge transfer between *adiabatic* states (i.e., the component of $\Delta \mu_{12}$ perpendicular to the symmetry axis vanishes), but there may be a finite, extraneous component of $\Delta \mu_{12}$ along the symmetry axis.

Defining the effective D/A separation as

$$r_{DA} = |\Delta \mu_{if} / e| \quad (80)$$

we may reexpress Eq. 74 in the familiar Mulliken–Hush (MH) form:

$$|T_{if}| = |\mu_{12} \Delta E_{12}| / (e r_{DA}) \quad (81)$$

where r_{DA} in the past has typically been estimated on the basis of molecular structural data (e.g., [120]). We emphasize that r_{DA} is an effective D/A separation, since it includes not only the distance between centroids of the D and A orbitals, but also reflects the consequence of the polarization of the spectator electrons in response to the primary electron transfer between D and A orbitals [121].

A frequently used expression equivalent to Eq. 81, but based on directly obtained spectral quantities (peak absorption frequency, $\nu_{\max}/\text{cm}^{-1}$, band width, $\Delta\nu_{1/2}/\text{cm}^{-1}$, and molar absorptivity, $\epsilon_{\max}/\text{cm}^{-1} \text{ mol}^{-1}$), with T_{if} in cm^{-1} and r_{DA} in Å, is given by [12, 120],

$$T_{if} = 2.06 \times 10^{-2} (\nu_{\max} \epsilon_{\max} \Delta\nu_{1/2})^{1/2} / r_{\text{DA}} \quad (82)$$

The spectral transition energy $h\nu$ corresponds to ΔE_{12} in Eq. 74. A refinement of Eq. 82, for which a scaled (“reduced”) lineshape $[e(v) \cdot v]$ and a refractive index correction are used is discussed in [27] and [96a]. The first-order perturbation theory embodied in Eq. 82 is an excellent approximation for field strengths used in conventional spectroscopy.

A recent analysis [30a] has shown that the exact solution of the two-state problem (subject only to the MH assumption, $\mu_{if} = 0$ as introduced in connection with Eqs. (74, 81, and 82) yields an expression for $\Delta\mu_{if}$ entirely in terms of the matrix elements of the dipole moment in the adiabatic basis (see also Eq. 78):

$$|\Delta\mu_{if}| = [(\Delta\mu_{12})^2 + 4(\mu_{12})^2]^{1/2} \quad (83)$$

Thus, Eq. 74, with $|\Delta\mu_{if}|$ replaced by the right-hand side of Eq. 83, allows T_{if} to be specified exclusively in terms of adiabatic observables [30a], that is, ΔE_{12} and μ_{12} (obtainable from spectral energy and intensity) and $\Delta\mu_{12}$ (obtainable from Stark spectroscopy [122, 123]). Of course, these quantities may also be obtained from quantum calculations [30]. In typical applications, Eq. 74 or 83 pertains to a vertical transition for a value of the reaction coordinate (Figure 2a) at the equilibrium position of the initial state (where, in general, $\psi_1 \approx \psi_i$). It is worth noting, however, that in the limit of resonant transfer (i.e., $H_{ii} = H_{ff}$, the TS for thermal electron transfer), we obtain the expected result (Eq. 63):

$$T_{if} = \Delta E_{12}/2. \quad (84)$$

since in this case (where $\cos\theta = \sin\theta = 1/\sqrt{2}$ in Eq. 14), $\mu_{12} = \Delta\mu_{if}/2$.

The generalized Mulliken–Hush model and formulation of diabatic states

The use of Eq. 83 in conjunction with the MH expression, Eqs. 80 and 81, is an important example of the so-called Generalized Mulliken Hush (GMH) model [30], implemented at the level of the TSA. The core idea of the GMH model [30] is to exploit the fact that diagonalization of the dipole moment matrix (selecting the vector components in the charge-transfer direction, as discussed above) yields the maximally charge-localized state functions (at the TSA level, this yields the maximum value of $\Delta\mu$), and we adopt the resulting eigenfunctions as physically appropriate definitions of diabatic states in the case of ET processes (earlier approaches of this type, implemented in a pairwise fashion, have been reported in [124]; see also related approaches in [143]). From this perspective, Eq. 74 follows directly at the TSA level and need no longer be viewed as being dependent on the “neglect” of the

transition moment in the diabatic basis (rather, the diagonal nature of the dipole moment matrix is entailed in the very definition of the diabatic basis). Furthermore, the GMH approach may be employed in a multi-state framework (e.g., when treating both CS and CR processes, as in Figure 2b). Typically, one starts with H^{el} and $\bar{\mu}$ in an n -state adiabatic basis (the one directly pertinent to spectroscopic observables, where H^{el} is diagonal), defines the diabatic basis in terms of the unitary transformation which diagonalizes $\bar{\mu}$, and then generates H^{el} in the diabatic basis by applying the same unitary transformation to the adiabatic H^{el} matrix.

When the multistate GMH transformation as defined here yields more than one diabatic state localized on the same site, we impose the additional condition that a block of the diabatic Hamiltonian associated with a single site be diagonal, thus yielding states diabatic in the GMH sense with respect to inter-site coupling, but “locally adiabatic” within each site or local region [30]. Clearly, this approach rests on a distance scale separation: D and A sites of small spatial extent relative to r_{DA} . In a multistate situation, the GMH analysis employs the component of each dipole vector in the mean direction defined by the adiabatic dipole shifts for the various electron transfer processes of interest.

As already noted above in connection with the two-state MH model (now recognized as a special case of GMH), we emphasize that the GMH method can be implemented solely in terms of experimental quantities. Observed excitation energies, transition dipoles from intensity measurements, and adiabatic dipole moment differences from Stark measurements yield direct experimental estimates of diabatic coupling elements according to the above procedure. At the multistate level, the relative sign relations among the transition moments must be known, and may be taken from calculations if not available from analyses of the experimental data. (These phase relations are “observables,” as distinct from phase “conventions;” e.g., for a three-state system two distinct cases arise: an even or odd number of positive transition dipole moments.) Finally, we mention that as in the two-state case (see Eq. 83), the GMH diabatic dipole-moment matrix in the general multistate framework directly yields estimates of the centroids of the different states of the system of interest and the associated r_{DA} values (i.e., effective separation distances of D and A sites), quantities of great utility in interpreting charge-transfer data obtained from Stark spectroscopy or quantum calculations [27, 30, 90b, 122, 123].

In computational applications, the formulation of the GMH approach in terms of adiabatic (H^{el} eigenvectors) quantities is very convenient, since it can be implemented in terms of eigenfunctions obtained from configuration interaction (CI) calculations [27, 30, 36, 69, 90b]. Such wavefunctions may be necessary for proper characterization of excited states, in contrast to the SCF wavefunctions, which are generally limited to use in ground-state thermal processes. Another advantage is the applicability for arbitrary values of the reaction coordinate or other coordinates of the system, thus offering a means of testing the Condon approximation [66].

One of the central physical characteristics of the GMH model, the block diagonal form of the diabatic dipole-moment matrix, where a block includes all states charge-localized at a given site, may be compared with the picture emerging from alternative formulations of diabatic states, which (unlike the GMH model) do not involve any assumptions about dipole matrix elements, being based instead on the details of

the eigenvectors of the Hamiltonian obtained from multistate quantum-chemical calculations [30b]. One such technique, in the spirit of the so-called “least-motion block diagonal” formulations, has been shown to give generally close adherence to results based on the GMH approach [30b].

1.4.3 Pathway Analysis of T_{if}

To shed light on the detailed electronic factors controlling overall D/A coupling as represented by $T_{if} \approx T_{DA}$ (see Eq. 66), we turn to the concept of the “electronic pathway”, a sequence of intermediate states of the bridge by which the transferring electron proceeds from the D to the A site. The pathway concept is generally used in the context of coherent D/A coupling involving *virtual* intermediate states (with vanishing lifetimes), as treated by superexchange (perturbation) theory in cases where the gap separating the D/A and the bridge levels are large, and this will be the focus of the present section [17, 60, 88]. In contrast, small gaps tend to favor incoherent hopping processes involving a finite residence time of the transferring charge on the bridge sites [19].

States and orbitals

While the most fundamental formulation of D/A coupling is in terms of many-electron states [6, 60], it is often possible to recast the formulation in terms of an orbital picture [34, 60] (see Section 1.4.1). For simplicity, we use the state language here. In the TSA, the initial and final diabatic states have the transferring charge largely confined to the D and A sites, respectively, and yet the coupling is crucially dependent on the D and A tails which extend onto the bridge. Superexchange (*se*) theory [6, 17, 60, 64, 125] provides a detailed account of these tails in terms of an auxiliary basis of zeroth-order states, $\psi_D^\circ, \psi_A^\circ, \psi_{B_1}^\circ, \dots, \psi_{B_n}^\circ$, which can be taken as essentially fully-localized on their respective sites (subject to maintenance of orthogonality), where the bridge is represented by n distinct units, B_j ($\psi_D^\circ, \psi_A^\circ$, and $\psi_{B_j}^\circ$ for the case of *electron* transfer correspond, respectively, to valence bond structures DBA, D^+BA^- , and $D^+B_j^-A$). These states may be taken as eigenfunctions of some zeroth-order Hamiltonian, $(H^{\text{el}})^0$, where

$$H^{\text{el}} = (H^{\text{el}})^0 + V \quad (85)$$

Here the perturbation V generates the D and A tails through mixing of the $\{\psi^\circ\}$. Note that first-order terms ($\langle \psi^\circ | V | \psi^\circ \rangle$) are generally assumed to vanish. In the following discussion of *se* models, it is understood that all D-, A-, and B-state labels refer to the zeroth-order states, and we won’t use zero as the superscript.

Superexchange models

The perturbative McConnell model for coupling by a single pathway is based on a bridge consisting of a homologous linear sequence of units, B_j , each with a single charge-localized state, ψ_{B_j} , lying above the resonant D/A energy level by a common

gap Δ [125]:

$$|T_{if}| = |T(t/\Delta)^{n-1}(T/\Delta)| \quad (86)$$

where it is assumed that $|T/\Delta|, |t/\Delta| \ll 1$. In this model, only nearest-neighbor (NN) pairs of sites are coupled:

$$T \equiv T_{DB_1} = T_{B_n A} \quad (87)$$

where, for example, $T_{DB_1} \equiv \int \psi_D V \psi_{B_1}$ and

$$t \equiv t_{B_i B_{i+1}} = \int \psi_{B_i} V \psi_{B_{i+1}} \quad (88)$$

This compact expression (Eq. 86), which is second-order with respect to linkage of D and A to the bridge and $(n-1)$ th order with respect to coupling within B, clearly predicts exponential fall-off. The decay coefficient with respect to n ($-\ln|t/\Delta|$) can be converted to the conventional measure of distance dependence, β ,

$$\beta = -2 \ln|t/\Delta|/\Delta r \quad (89)$$

where Δr is the effective length of a bridge unit. The factor of two is included to correspond to the distance-dependence of the factor $(T_{if})^2$ in the non-adiabatic expression for k_{et} (Eq. 31):

$$(T_{if})^2 \propto \exp(-\beta \Delta r) \quad (90)$$

The distance-dependence of the overall k_{et} may depart from that given by Eq. 90 due to additional distance-dependence arising from λ or ΔG° [9, 119], or in cases of incoherent sequential electron hopping [19]. The role of the gap Δ , particularly in the quantity t/Δ , is seen to be crucial in controlling both the magnitude and distance dependence of T_{if} .

It is of course a matter of choice as to how finely the total bridge is divided into subunits. The optimal choice involves various trade-offs, including chemical transferability (favoring small subunits), compactness of representation when it comes to synthesizing the overall coupling T_{if} (favoring larger subunits), and theoretical considerations such as the applicability of perturbation theory (here the trade-off is complex, but often favors larger subunits [34, 126]). Furthermore, the number of states, ψ_{B_i} , required in each unit to give adequate account of the coupling would tend to increase with the size of the unit, thus requiring an extension of the single-pathway McConnell model.

The sign of T_{if} for a given pathway is of interest, especially when the overall T_{if} involves the superposition of several pathways. Determination of sign requires careful consideration of all phase conventions used in defining the states involved in coupling elements T and t . In many cases of interest, the sign of t/Δ in Eq. 86 can be taken to be negative, thus yielding the prediction that the sign of T_{if} alternates

with n while its magnitude fall off exponentially [6]. This is the basis of the so-called parity rule [127]. Of course, in more complex situations (beyond the simple NN homologous case), the sign patterns are expected to be more complicated [34, 63, 70b].

Through its dependence on the NN transfer integrals T and t , and a measure of distance scale, Δr , Eq. 86 represents, at least in a minimal fashion, the inhomogeneous nature of the electronic structure of the bridge. This is to be contrasted with the Gamow model for electronic tunneling through a homogeneous barrier of height Δ^G [128], where β is given by the following equation:

$$\beta^G = 2(2m_e\Delta^G)^{1/2}/\hbar \quad (91)$$

and where m_e is the mass (actual or effective) of the tunneling electron. An important distinction is made between the roles of the gaps Δ in Eqs. 89 and 91. In the former case, Δ (for a particular bridge subunit) is, in principle (and in some cases in practice), a spectroscopic observable, whereas the phenomenological Δ^G , which represents the full bridge in Eq. 91, is not in general directly accessible as an observable. Effective Δ^G values may, of course, be inferred from Eq. 91 on the basis of experimental β values, but attempts to use experimentally determined energy gaps (e.g., from redox potentials or spectroscopy) frequently lead to exaggerated β magnitudes [129]. Eq. 91 is more usefully applied to the direct or “through-space” (ts) D/A coupling when no bridge is present. In this case, Δ^G may be identified with the relevant ionization potential of D [130]. Equation 86 may be generalized in a number of ways including the following [6, 60]:

a) Distinct bridging units:

$$T_{if} = (T_{DB_1}) \left[\prod_{j=1}^{n-1} t_{B_j B_{j+1}} / \Delta_j \right] (T_{B_n A} / \Delta_n) \quad (92)$$

where the subscripts on T and t denote NN coupling, and Δ_j denotes the gap between the D/A level and the energy of bridge unit j .

- b) Summation over multiple pathways of the generic type exemplified by Eq. 92, where advantage is taken of the additive contributions of the various perturbative terms and non-NN pathways are also included. Such non-NN contributions are expected to enhance the sensitivity of T_{if} to conformational variations of the bridge and will also tend to reduce the distinction between covalently linked bridges and those which involve nonbonded contact [60].
- c) Involvement of more than one charge-localized state on each site, including, for example, those based on both occupied and unoccupied bridge bands, thereby leading to competitive (either constructive or destructive) interference among “hole”, “electron”, and “hybrid” pathways [34, 60, 109]. The case for hole- and electron transfer involving two bridge sites is illustrated in Figure 5. Alternatively, one may have competition between different components of a given occupied or unoccupied manifold—for example, σ - vs π -types [70].

Figure 5. Schematic representation of bridge-mediated superexchange of the “electron” (top, left to right) and “hole” (bottom, right to left) type, illustrated for the case of intermolecular electron transfer between two metal/ligand (M/L) complexes, where $D \equiv M_l$, $B \equiv L_l \cdots L_r$, and $A \equiv M_r$. The virtual intermediate states for the hole and electron processes involve, respectively, charge localization based on the filled (“valence”) and empty (“conduction”) bands of the bridge.

Equations 86 and 92 may be derived in terms of effective Hamiltonians based on partitioning schemes [131], or when Green-function techniques are used [17]. A number of detailed computational studies have been carried out in which T_{if} was additively decomposed into contributions from competing pathways defined in terms of states based on localized bonding, antibonding, and lone-pair orbitals [34, 109–111]. The general conclusion is that the McConnell NN pathway, if interpreted in terms of localized bonding or antibonding orbitals, often has a very minor role, and that in most cases no single pathway plays a dominant role. Nevertheless, the form of the simple McConnell expression (Eq. 86), or limited extensions thereof (e.g., Eq. 92 or a NN model with two states per site [70]) may be very useful for representing the results of detailed calculations of T_{if} (see also [63] and [111]) Examples are considered in Section 1.5, together with a discussion on interference effects.

When the gaps Δ_j are large, their variation with nuclear coordinates (e.g., bridge modes or the reaction coordinate) may be neglected. More detailed approaches are discussed in [9, 32a, 132]. Relative to the perturbative result given in Eqs. 89 and 90, a more general expression displaying exponential decay is also found when the constraints of perturbation theory are relaxed, provided that $|T/\Delta|$ remains small and the D/A level remains outside the band of bridge levels ($|\Delta| > |2t|$ for the linear NN case) [88]. Special care must be exercised when the D/A level begins to overlap the electronic bands of the bridge [133]. In such a situation the distance-dependence of T_{if} will, in general, not be exponential, and thus fitting of experimental or calculated T_{if} data to an expression of the form given by Eq. 90 is no longer appropriate.

An aside on notation

We comment briefly on the notation employed here and in [17, 34, 60 and 89] for the D/A coupling element (T_{if} or T_{DA}). The symbol “ T ” denotes the “transfer integral”, which may be viewed as the matrix element of a “transfer operator”, which couples the *zeroth-order* basis functions ψ_j^0 defined above; T_{if} is equivalent to H_{if}^{el} , if

the latter is understood to be the matrix element of H^{el} (see Eq. 13) with respect to the *full* diabatic functions ψ_i and ψ_f (i.e., including tails) in the TSA. The “ H ” notation in this sense was employed in [6] (H_{if}) and [8] (H_{ps}). The symbol “ T ” was used in a different manner in [8] (nuclear kinetic energy operator) and [125] (NN coupling elements in the zeroth-order basis).

1.5 Applications of Theory

The models and concepts presented in Sections 1.1–1.4 have been extensively tested in recent years. Some of these tests involved comparison of quantitative relationships between experimental observables with predictions of simple models. In other tests, the theoretical predictions and experimental data were compared with the results of detailed numerical calculations. We offer several examples of each type of comparison.

1.5.1 Comparisons Based on Experimental Data

A number of interesting consistency tests of models for ET kinetics and D/A coupling are provided by available thermal and optical data.

Tests of superexchange models

Mixed-valence complexes

The optical ET data for the class of mixed-valence systems of the type shown in Eq. 93 has provided a rich test bed of experimental data [120–123, 134, 135].

We consider charge-localized systems (Robin–Day class II [136]) in which the bridging ligand L provides one coordination site for each ruthenium atom. The other five coordination sites at each ruthenium are provided by ammine or other nitrogen-based ligands. The effective Ru–Ru coupling elements for these processes may be estimated directly if the MH expression (Eq. 82) is used to analyze the intervalence transition (IT). Alternatively, one may employ a superexchange model, where Eq. 82 is used in conjunction with data for optical ET between L and the Ru sites [120]. For the specific system under consideration (Eq. 93), we employ the subscripts M and M' for the two Ru sites and L for the bridging ligand,

$$T_{if} = T_{MM'}^{\text{op}} = \frac{T_{ML}^{\text{op}} T_{M'L}^{\text{op}}}{2\Delta E_{ML}^{\text{eff}}} + \frac{T_{LM'}^{\text{op}} T_{LM}^{\text{op}}}{\Delta_{LM}^{\text{eff}}}, \quad (94)$$

where T_{jk}^{op} denotes the coupling for the relevant optical ET process ($jk \equiv MM', ML, LM$, etc). The two terms correspond, respectively, to electron- and hole-transfer mechanisms, facilitated by virtual intermediate states, respectively, of the metal-to-ligand (MLCT) and ligand-to-metal (LMCT) charge-transfer type. Each of these terms can be recognized to have the simple McConnell form (the factor of two in the first term is discussed in [120]), although the formal derivation for the present case of nonresonant D/A sites is distinct from that for the resonant sites entailed in the McConnell derivation [6]. The effective energy gap for optical electron transfer is given by the following equation [6, 120]:

$$\Delta E_{ML}^{\text{eff}} = [0.5(1/E_{MLCT} + 1/(E_{MLCT} - E_{IT}))]^{-1} \quad (95)$$

(and analogously for $\Delta E_{LM}^{\text{eff}}$ in the hole-transfer term). Here E_{MLCT} and E_{IT} are the vertical excitation energies for the MLCT and MM'CT (IT) processes. The T_{ML}^{op} and T_{LM}^{op} quantities may be obtained from the relevant spectral data in conjunction with the MH expression [120]. For simplicity, the assumption is made that $T_{ML}^{\text{op}} = T_{M'L}^{\text{op}}$ and $T_{LM}^{\text{op}} = T_{LM'}^{\text{op}}$, even though the coordination geometries at the 2+ and 3+ sites are not identical [120, 135]. In the following, we leave out the superscript “op” and distinguish $T_{MM'}$ obtained directly from the MH model for the IT process and the *se* model (Eq. 94) as $T_{MM'}^{MH}$ and $T_{MM'}^{se}$, respectively.

An important feature of Eqs. 82 and 94 is that they can in principle be implemented entirely in terms of experimental spectral data. One point requiring special comment is the determination of r_{DA} in Eq. 82. While this may be obtained by Eq. 83 if the results of Stark spectroscopy are available, such data are still relatively scarce, thus making it common to use structural data (e.g., $r_{MM'}$ or r_{ML} based on the metal site and the ligand midpoint [120, 135]), as estimated upper limits. In cases where Stark data are at hand, r_{DA} is often found to be appreciably smaller than $r_{MM'}$ (or r_{ML}), especially in cases of strong ML coupling [89, 121–123] (examples are given in Section 1.5.1). Nevertheless, recent analyses based on $r_{MM'}$ and r_{ML} have given numerous examples of reasonable correspondence between $T_{MM'}^{MH}$ and $T_{MM'}^{se}$. One study of relatively weak MM' coupling ($T_{MM'}^{se} \leq 1000 \text{ cm}^{-1}$) involving pyridyl-based ligands (L), where the electron-transfer mechanism (first term in Eq. 94) was thought to be dominant, systematically yielded $T_{MM'}^{se} \geq T_{MM'}^{MH}$ and within a factor of two or better [120]. Similar results were also found for cases of relatively weak coupling (i.e., $T_{MM'}^{se} \leq 2000 \text{ cm}^{-1}$) in a more recent study [135] employing the ligand dicyd²⁻ \equiv 1,4-dicyanoamido benzene ($[\text{NCN}-\text{C}_6\text{H}_4-\text{NCN}]^{2-}$), where the hole mechanism (second term in Eq. 94) was taken as dominant. For cases from the same study in which the coupling was stronger ($T_{MM'}^{se} \geq 3000$), values of 3–5 for $T_{MM'}^{se}/T_{MM'}^{MH}$ were found, suggesting (inter alia) greater uncertainty in the appropriate r_{DA} values. Nevertheless, these results offer encouraging support for the use of simple superexchange models like Eq. 94, and also offer an incentive for further Stark measurements so as to provide better r_{DA} estimates (in conjunction with Eq. 83) and thereby allow more quantitative testing of the superexchange model. Finally, we note, as a caveat, a recent study of a family of MLM' systems in which the trends implied by Eq. 94 were not observed; this suggests that specific vibronic effects may be required to account for the relevant MM' coupling [137].

Electron-transfer coupling vs magnetic exchange

It is well known that superexchange theory provides useful relationships between one- and two-electron coupling elements (e.g., [28, 78, 138]). We consider the simple case of a monocation electron transfer system,

and the corresponding dication, D^+BA^+ , in which the coupling of the localized doublet spins at the D and A sites is triplet (ferromagnetic) or singlet (antiferromagnetic) [28]. We also assume for simplicity that D and A are symmetry-equivalent sites. Defining $E_{\text{singlet}} - E_{\text{triplet}} = 2J$, where J is the Heisenberg exchange integral, and assuming that only the singlet state is stabilized by D/A coupling, we obtain:

$$J = (\alpha T_{if})^2 / \Delta E_{CT} \quad (97)$$

where α is a numerical coefficient, T_{if} is the one-electron transfer integral and ΔE_{CT} is the energy of the vertical charge-transfer process from the diabatic ground-state singlet diradical, D^+BA^+ , to the diabatic excited state, a symmetric mixture of $D^{2+}BA$ and DBA^{2+} resonance structures. Nelson and coworkers [28] have tested Eq. 97 for DBA system **1** by obtaining independent estimates of the four parameters in the equation. The spectral data yielded $T_{if} = 3.3$ kcal/mol and $\Delta E_{CT} = 64.1$ kcal/mol for the monocation ($\mathbf{1}^+$) and $J = 0.18$ – 0.21 kcal/mol for the dication ($\mathbf{1}^{2+}$). Comparison of the optical spectra for ($\mathbf{1}^+$) and ($\mathbf{1}^{2+}$) yielded $\alpha \approx 1.2$, to be compared to the zeroth-order theoretical prediction, $\alpha = \sqrt{2}$. In either case, the right-hand side of Eq. 97 is found to be in good accord with the experimental J value: 0.23 kcal/mol ($\alpha = 1.2$) or 0.34 ($\alpha = \sqrt{2}$), thus providing impressive support for the superexchange model.

 *β Values for One- and two-electron processes*

T_{if} for electron (or hole) transfer may essentially be thought of as a one-electron integral (T_{DA} , as in Eq. 66) involving the exchange density, $\phi_D\phi_A$, where the tails of ϕ_D and ϕ_A involve mixing of zeroth-order D and A orbitals with the unfilled (electron) or filled (hole) manifolds of the bridge. In triplet energy transfer by the Dexter mechanism [139], the corresponding two-electron (2e) coupling element involves two exchange densities, $\phi_D\phi_A$ and $\phi_D^*\phi_A^*$:

$$T_{if}^{2c} = \int d\tau d\tau' \phi_D(r) \phi_A(r) (1/r_{12}) \phi_D^*(r') \phi_A^*(r') \quad (98)$$

where ϕ_D , ϕ_D^* and ϕ_A , ϕ_A^* are the orbital pairs involved in the local triplet excitation being transferred between D and A sites. If the tails of D and A (D^* and A^*) are assumed to be dominated by mixing with the filled (unfilled) bridge manifolds, we conclude that a good estimate of the exponential decay coefficient of $(T_{if}^{2c})^2$ with bridge length, β^{2c} , might be given by the sum of the electron (β^e) and hole (β^h) decay coefficients for the corresponding one-particle processes. In fact, just such a relationship was demonstrated on the basis of experimental data for a series of $(DBA)^+$ systems where D = 4-biphenyl (electron or hole transfer) or 4-benzophenonyl (triplet transfer), A = 2-naphthyl, and B was based on cyclohexyl or decalin moieties, that is, the observed rate constants for triplet energy transfer were found to agree well with predictions based on $\beta^{2c} = \beta^e + \beta^h$ [76]. This result was also supported by ab initio calculations for related model systems [62].

Thermal vs optical electron transfer

Given the wide use of the MH analysis of optical data (Eq. 82), it is of considerable interest to ascertain the quantitative validity of transferring T_{if} values obtained from optical electron transfer at equilibrium for use in analyzing thermal electron transfer occurring at the TS.

Mixed-valence $Fe^{2+/3+}$ complexes

A convincing demonstration of such transferability was recently obtained by Elliott et al [27], using a mixed-valence Fe^{2+}/Fe^{3+} system involving tethered tris-bipyridyl Fe complexes, **2** ($M = 4$). The analysis in this case was greatly simplified since no high-frequency inner-sphere modes were appreciably coupled to the ET process, thereby permitting a classical treatment of the energetics. The salient results are summarized in Table 1. In the analysis of the optical ET data, r_{DA} was estimated to be very close to r_{MM} , a consequence of the rather symmetric nature of the Fe coordination shells, in contrast to the more asymmetric coordination shells of most of the systems investigated by Stark spectroscopy [122, 123]. The optical T_{if} estimates are seen to depend modestly on the specific form of refractive index correction employed. When T_{if} was estimated from the thermal data, the result was found

Table 1. Comparison of optical and thermal T_{if} and λ values for $2(m = 4)$.

ⁱ[21, 27].

to be rather sensitive to the manner in which the temperature-dependence of λ was treated. It is now recognized that such dependence is often quantitatively significant and that estimates of this dependence based on a continuum model have an incorrect (positive) sign for polar solvents [21, 27, 53, 54, 140]. The preferred estimate, based on a molecular-level model [21], yields a result ($T_{if} = 4.7 \pm 0.9$ cm⁻¹) in quite good agreement with the preferred optical value (5.4 ± 0.7 cm⁻¹). As a final test of consistency, the values of λ inferred from the optical (7900 ± 200 cm⁻¹) and thermal (7500 ± 300 cm⁻¹) data are in good accord.

Analysis of a series of Ru^{2+/3+} mixed-valence systems

The same series of Ru²⁺/Ru³⁺ systems that were used to compare T_{if} values obtained from direct use of the MH model (Eq. 82) with the T_{if} values obtained from a superexchange model (Eq. 94), as discussed in Section 1.5.1, were also employed for a comparison of optical and thermal T_{if} values [135]. In this case the thermal T_{if} values were inferred indirectly from the estimated “resonance-exchange component” ($\Delta G_r'$) of the free energy change (ΔG_c) associated with the measured disproportionation equilibrium between the 3+/3+, 2+/2+, and 2+/3+ oxidation states. According to the perturbative model adopted for the Robin/Day class-II system [136], one obtains

Figure 6. Estimates from thermal and optical ET data for the resonance stabilization ($\Delta G'_r$) [135] of mixed-valence systems of the type $\text{Ru}^{2+}\text{BRu}^{3+}$ due to metal-metal coupling ($T_{MM'}$), where B is based on the "dicyd²" bidentate ligand (1,4-dicyanoamido-benzene), and the D and A moieties are Ru pentaammine (■), tetraammine (●), or triammine (▲) complexes [135]. The thermal estimates of $\Delta G'_r$ are obtained from measured comproportionation constants, while the optical estimates are based on use of the second-order perturbation theory expression, Eq. 99, evaluated in terms of spectral data in conjunction with the MH model (Section 1.4.2), where the r_{DA} that is used is based on the Ru-Ru' separation. (Figure 6 of [135], reprinted with permission. Copyright 1998, American Chemical Society).

$$\Delta G'_r = (T_{MM'})^2 / \Delta E_{IT}. \quad (99)$$

where $T_{MM'}$ is the quantity introduced in Section 1.5.1. While Eq. 99 resembles a second-order perturbation-theory result, it is in fact exact within the two-state harmonic approximation for diabatic states [9c]. As indicated in Figure 6, Eq. 99 based on $T_{MM'}^{\text{sc}}$ (see Section 1.5.1) gives a reasonably good account of the trend relating the thermal (left-hand side) and optical (right-hand side) measures of $M-M'$ coupling, thus once again offering encouraging support for the transferability of thermal and optical T_{if} values (the use of $T_{MM'}^{\text{MH}}$ as an estimate of the optical $T_{MM'}$ value, see Section 1.5.1, did not yield a good correlation with $\Delta G'_r$). For achieving more quantitative correlations, the choice of r_{DA} values entailed in the MH model must be scrutinized and, in the case of strongest coupling, efforts should be made to relax the constraints of the model underlying Eq. 99 [135].

Other work

A number of other comparisons of thermal and optical data have been reported; these provide additional support for the transferability of T_{if} quantities, a manifestation of the reliability of the Condon approximation. We note, for example, the recent work of Nelsen et al. [141], and the earlier work of Penfield et al. [142].

Estimates of r_{DA}

In cases where optical electron-transfer data include Stark spectral results, one may compare r_{DA} estimates based on molecular structure r_{DA}^{geom} with those obtained from diabatic r_{DA}^{diabat} and adiabatic r_{DA}^{adiabat} dipole-moment shifts associated with the ET process. Some examples from IT and MLCT spectra are summarized in Table 2; a uniform trend is obvious, namely,

$$r_{DA}^{\text{geom}} > r_{DA}^{\text{diabat}} > r_{DA}^{\text{adiabat}} \quad (100)$$

where r_{DA}^{geom} is based on the MM' distance or the distance between M and the L midpoint, and r_{DA}^{diabat} and r_{DA}^{adiabat} are defined by the GMH model (Eq. 83). Clearly, the ratio of r_{DA}^{diabat} to r_{DA}^{geom} departs significantly from unity (0.5–0.8 for the ML and class-II MM' complexes and 0.2 for the class-III MM' complex, where L = pz; this underscores the importance of careful choice of r_{DA} values when the MH model is implemented (Eq. 82). Significant quantitative differences between r_{DA}^{diabat} and r_{DA}^{adiabat} are revealed as well.

1.5.2 Computational Studies

A number of computational approaches have been exploited for evaluating the crucial coupling (T_{if}) and energetic quantities (especially, G^\ddagger and λ) controlling

electron transfer kinetics. As illustrated in the following examples, these studies play several important complementary roles in helping to elucidate ET mechanisms, as has been extensively documented and reviewed in the recent literature [1, 3, 4, 10]). These roles include tests of simple theoretical models (thereby helping the formulation of compact predictive models), comparisons with experimental results (helping to guide the design of new experiments), and illuminating interpretive analyses.

Calculations of coupling elements involve the basic electronic structure model, the procedure for extracting T_{if} estimates from the calculated wavefunctions, and schemes for inferring detailed molecular contributions to overall T_{if} values. Ab initio and semi-empirical orbital models, and also density functional theory (DFT) [143] have been employed. The orbital models have been implemented at the mean-field level (e.g., Hartree–Fock, HF, or self-consistent field, SCF) or in an extended framework (e.g., configuration interaction, CI), which permits treatment of excited states and account of electron correlation. In evaluating T_{if} , one may use a simple energy splitting model as given by Eq. 63, based on an effective Hamiltonian or Green function defined in terms of the calculated electronic structure [60] if the D and A sites are resonant (in general this may be achieved if some “external” perturbation is imposed, such as an electric field). Alternatively, the GMH model (Eqs. 81 and 83) may be employed for nonresonant situations. A promising DFT-based approach has recently been reported [143], whereby T_{if} is inferred from the response of the ground-state charge density to a variable external field which causes a continuous switch of the charge-transfer character (e.g., from DBA to D^+BA^-). Contributions to T_{if} have been analyzed in terms of additive pathway schemes based on localized orbitals (at both SCF [34, 109–111] and CI [112e,f] levels) and other decomposition schemes [112a–d], in an attempt to spatially identify the most important pathways or bridging units (e.g., amino acid residues).

Procedures for evaluating activation parameters range from simple continuum models to full-blown molecular-level simulations (molecular dynamics, MD, or Monte Carlo, MC) at either a classical or quantal level [15, 21, 33, 36, 47, 49, 52a, 84b, 94, 119]. In such treatments, the DBA system may be represented by a simple point-charge model or one based on a detailed electronic structure calculation, which can, if desired, be self-consistently adjusted to the response of the medium [119].

Response of T_{if} to structural change in a DBA system

Since no DBA system is fully rigid, it is important to know the consequence of structural fluctuations on kinetic parameters (e.g., those fluctuations corresponding to distinct conformational isomers, or those of smaller amplitude within a given local minimum). We consider some examples (see also [71c]) of structural coordinates of the bridge (B), which modulate T_{if} values, but are not strongly coupled to the fluctuating energy gap (i.e., reaction coordinate η in Eqs. 20–23). These coordinates thus provide useful controlled probes of non-Condon behavior [66], since they have a small effect on activation energetics (some sensitivity of λ may arise for fluctuations which affect the magnitude of r_{DA} , as has been noted in [89] and [119]).

Table 3. Conformational Dependence of T_{if} for $(\text{CH}_2)_6^\pm$ Radical Ions^a.

Conformation of D and A orbitals relative to bridge	Conformation of C ₄ bridge	T_{if} ^c	
		Radical cation	Radical anion
In plane	<i>trans</i> (C _{2h})	−11.0	−8.4
	<i>gauche</i> (C ₂)	−2.4	−4.5
	<i>cis</i> (C _{2v})	−0.3	−4.3
Perpendicular to plane	<i>trans</i> (C _{2h})	−1.1	+0.3
	<i>gauche</i> (C ₂)	+3.6	+2.0
	<i>cis</i> (C _{2v})	+7.9	+9.9

^aIn these model (DBA)⁺ systems, the terminal CH_2^\pm and CH_2 groups serve as D and A sites, while the internal $(\text{CH}_2)_4$ moiety is the bridge (B). (Table 2 of [149], reprinted with kind permission. Copyright 1996, Elsevier Press).

^bAngle of the D(A) π orbital relative to plane formed by the carbon atom of the terminal D(A) methylene group and the closest two carbon atoms of the bridge.

^cCalculated results based on ab initio SCF calculations; T_{if} in units of mhartree (1 mhartree = 0.027 eV $\approx k_B T$ at room temperature). The sign conventions are defined in [149].

Alkane-chain conformation

A simple but important example of conformational sensitivity of T_{if} is illustrated in Table 3, in which results for *trans* staggered (*t*), *gauche* (*g*), and *cis* (*c*) conformations of some C₄ alkane bridges are compared and in which sign changes as well as significant changes of magnitude are seen [144]. A similar pattern in more complex bridge moieties has been observed in both computational and experimental data [62, 110]. This situation offers a caveat regarding distance-dependence of T_{if} in families of DBA systems. Although a $(\text{CH}_2)_n$ sequence may be considered to be homologous, one would not necessarily expect a simple exponential fall-off with n if the different members of the series have different conformational structures. Nevertheless, it has been noted that compensating factors (e.g., a variable number of equivalent “pathways” of the $(\text{CH}_2)_n$ type) may lead to overall exponential fall-off [34, 62, 110].

Oligophenylene ethynylene (OPE) bridges

Recent kinetic studies have yielded β values for electron transfer through bridges comprised of phenylene–ethynylene (OP) moieties (i.e., alternating benzene and acetylene units) [70a, 145]. The range of β values ($\sim 0.4\text{--}0.6 \text{ \AA}^{-1}$) is intermediate between typical values for conjugated unsaturated ($\geq 0.3 \text{ \AA}^{-1}$) and fully saturated ($\geq 0.8 \text{ \AA}^{-1}$) bridges [6]. Since the intrinsic barrier to rotation of a phenylene group in OPE is thought to be quite small [70] ($\leq k_B T$ at room temperature; this favors the planar conformation of a pair of adjacent phenylene groups), the likelihood of wide-amplitude conformational fluctuations, and the attendant modulation of D/A coupling through the bridge, must be addressed. A rather simple model for T_{if} as a function of an arbitrary set of phenylene conformational angles, θ_j , $j = 1 - m$

Table 4. Variation of exponential decay coefficient (β) with bridge type^a.

Bridge repeat unit	β (\AA^{-1})		Experimental
	Cation	Anion	
<i>trans</i> ($\text{CH}=\text{CH}-$)	0.31	0.32	0.2–0.3 ^c
($-\text{C}=\text{C}-p\text{C}_6\text{H}_4-$)			
planar ($\theta_j = 0$)	0.39	0.43	
random θ_j ^d	0.51	0.54	0.36 ^{e,f} , 0.57 ^{f,g}
perpendicular ($\theta_j = \pi/2$)	0.97	1.00	
staggered ($-\text{CH}_2-\text{CH}_2-$)	0.83	1.00	0.9 ± 0.1 ^h

^aThe OPE bridge is displayed as $3(m)$. (Table II of [70b], reprinted with kind permission. Copyright 2000, John Wiley & Sons, Inc.)

^bBased on the slopes of linear least-squares fits of calculated $\ln(T_{if}^2)$ vs r_{DA} values (in all cases, the regression coefficient $r > 0.99$), with r_{DA} taken as the distance between the C atoms of the terminal D and A groups (r_{DA} values obtained by Eq. 83 are somewhat smaller).

^c[150].

^d β values are based on root-mean square values of T_{if} , averaged over a uniform $\{\Theta_j\}$ distribution.

^eBased on OPE bridges with some of the phenylene groups substituted with alkyl or alkoxy groups [145].

^fThe Θ_j distribution is unknown.

^g[70a].

^h[25b].

(where $\text{OPE} \equiv (\text{PE})_m$) was formulated [70] by use of the compact form of the McConnell pathway (Eq. 92), and by effective parameters of the type T , t , and A being defined in terms of detailed CI calculations used in conjunction with the GMH model (Eqs. 81 and 83). Before outlining this model, which shows the utility of a suitably extended and parameterized version of the basic McConnell concept, we first summarize the calculated results for β in comparison with experimental estimates (Table 4). The OPE calculations were based on the radical ions represented by $3(m)$, $m = 1-4$ (the radical cations and radical anions yielded similar β

values), with terminal CH_2^+ and CH_2 moieties, respectively, as model D and A groups (other details of the calculations are given in [70]). The most notable result is the strong dependence of β on the distribution of Θ_j values, as shown for three limiting cases: 1) D, A, and all phenylenes conjugated (i.e., coplanar); 2) random Θ_j ; and 3) all phenylenes perpendicular to the D/A plane and thus fully out of conjugation with D and A; this yields, not surprisingly, a β value similar to that for a saturated, (σ -bonded) alkane bridge. The initial experimental OPE study [70a], based on *unsubstituted* phenylenes, yielded a β value (0.57 \AA^{-1}) suggesting (in comparison with the calculated results) significant dispersion of Θ_j values. In a more recent study [145], in which some of the phenylenes were substituted with methyl or propyloxy groups, an appreciably smaller β value was observed (0.36 \AA^{-1}). Since the substituents are not expected to cause this shift in β exclusively as a result of a direct electronic effect, it is thought likely that they affect the coupling indirectly through alteration of the intermolecular interactions of a given OPE with its neighbors in the self-assembled monolayers employed in the experimental studies.

The theoretical model underlying the OPE calculations is based on the idea that for arbitrary Θ_j , each PE unit may facilitate the coupling both through its π -manifold and (in a hyperconjugative sense) through orbitals of the appropriate “ π -type” nodal structure contained in its σ -manifold. This leads to a superposition (with phase) of 2^m pathways of the type given in Eq. 92,

$$|T_{if}| = \left| \sum_{\{x\}} (T_{DB_1}^{x_1}) \left[\prod_{j=1}^{m-1} (t_{B_j B_{j+1}}^{x_j, x_{j+1}} / \Delta_{B_j}^{x_j}) \right] (T_{B_m A}^{x_m} / \Delta_{B_m A}^{x_m}) \right| \quad (101)$$

where each superscript x_j denotes a π - or σ -manifold.

Since the most important orbitals in the model system **3** (the D and A π -orbitals and the relevant highest occupied and lowest unoccupied molecular orbitals (MO's) of each PE moiety) have the same qualitative nodal structure with respect to rotation about the OPE axis (i.e., a single node), we approximate the transformation behavior under such rotations (Θ_j) in terms of $\sin \Theta_j$ and $\cos \Theta_j$. Accordingly, the hopping integrals (T, t) in Eq. 101 may be elaborated as follows:

$$T_{DB_1}^\pi = (T_{DB_1}^\pi)_0 \cos \Theta_1 \quad (102a)$$

$$T_{DB_1}^\sigma = (T_{DB_1}^\sigma)_0 \sin \Theta_1, \text{ etc.}, \quad (102b)$$

and analogously for $T_{B_m A}^\pi$ and $T_{B_m A}^\sigma$,

$$t_{B_j B_{j+1}}^{\pi\pi} = (t_{B_j B_{j+1}}^{\pi\pi})_0 \begin{pmatrix} \cos \Theta_j \cos \Theta_{j+1} \\ + \sin \Theta_j \sin \Theta_{j+1} \end{pmatrix} \quad (103a)$$

$$t_{B_j B_{j+1}}^{\sigma\sigma} = (t_{B_j B_{j+1}}^{\sigma\sigma})_0 \begin{pmatrix} \cos \Theta_j \cos \Theta_{j+1} \\ + \sin \Theta_j \sin \Theta_{j+1} \end{pmatrix}, \text{ etc} \quad (103b)$$

The parameters with “0” subscripts, denoting limiting Θ_j values (0 or $\pi/2$), were

fitted [70] with the results of detailed CI/GMH calculations based on the INDO/s semi-empirical Hamiltonian [146]. For the range $m = 1$ to 4, the results of the model (Eq. 101) and full calculations agreed to better than 10 % [70].

An interesting feature of Eq. 101 is a degree of destructive interference arising from the pure π -pathway (the exclusive one when all $\Theta_j = 0$) being governed by a parity rule. As a result, when the σ contributions are suppressed (in the $2^m - 1$ pathways in which they would normally participate), the T_{if} magnitude and the β value actually *increase* [70b].

Presumably, other efforts to exploit the concept of the McConnell-type pathway (analogous to the approach just outlined) can be successful, provided a suitable method for defining the associated parameters can be found. Another approach is to extend the NN form of the McConnell pathway by introducing a limited set of longer-range (non-NN) interactions, once again using an independent set of calculations to determine the parameters of the extended model (e.g., see [111]).

Fluctuations in protein bridges and liquid water

Several recent studies have used MD simulations to assess the role of fluctuations on T_{if} , either dynamically [67] or in terms of thermally-equilibrated systems [69]. The electronic-structure models were based on semi-empirical Hamiltonians, with some tests based on ab initio results also carried out [69]. For protein systems [67], the calculations yielded significant dynamic modulation of T_{if} , although the extent of this effect was sensitive to details of the gap between the D/A and bridge levels (the “tunneling energy” parameter employed in the Green-function-based treatments). In addition to elastic modulation, a model for fluctuation-induced inelastic tunneling was proposed [67a,b], and it will be interesting to ascertain from detailed computational studies the magnitude of such contributions. In studies of what was presumed to be primarily hole transfer through liquid water [69], thermal averaging was found to lead to a pronounced increase in β magnitudes ($\beta \approx 1.5\text{--}1.8 \text{ \AA}^{-1}$) relative to those based on idealized hydrogen-bonded water bridges. In experimental studies of aqueous electron transfer with the hydrated electron as the donor species [151], a value of $\beta = 0.75 \text{ \AA}^{-1}$ was estimated, suggesting (from comparison of [69] and [151]) the possibility of significantly different distance-dependence for electron and hole transfer through water.

Pathway interference

Patterns of constructive and destructive interference were obtained from comparisons of T_{if} values obtained from detailed orbital calculations [60, 63, 70b, 110] and were analyzed in some cases in terms of the simple parity rule (the sign alternation with m of a pathway of the type given in Eq. 86) or suitable generalizations [6, 63].

Norbornane-based bridges

Relative to T_{if} for hole transfer through a single staggered alkane chain, norbornane-based bridges, characterized by two parallel alkane chains (relays linked by single

bonds or CH_2 cross-bridges) yield strong interference effects [63]. For example, considering olefinic D and A groups, we compare the reference single-chain system **4(n)** with **5(n)** and **6(n)**. Relative to the through-bond (*tb*) coupling in **4(n)**, the decay of T_{ij} with $n(\beta)$ is greater for **5(n)**, primarily as a result of through-space (*ts*) “cross-talk” between the two relays [63], which interferes destructively with the coupling through each relay. On the other hand, when the olefinic groups are in *exo* configurations, unsymmetrical with respect to the two relays, as in **6(n)**, the pathways involving cross-talk are all found (from analysis of NBO-based ab initio calculations) to be in phase with the intra-relay pathways, thus yielding substantial constructive reinforcement; this result which can be rationalized in terms of an extended parity rule taking account of the phases of the individual local orbitals as well as the number of orbital units in each competing pathway [63a]. These results are illustrated for $n = 14$ in Table 5. Even more dramatic effects were observed in some variants of **6(n)**, thus leading to the designation “superbridges” for this class of DBA systems.

Table 5. Inter-relay interference effects^a.

	T_{ij} (eV)	β (\AA^{-1})
Single relay ^b [4(n)]	0.018	0.25
Two relays ^c

^b*Trans* staggered alkane bridge.

^cNorbornane-based bridge (two cross-linked alkane chain relays).

^dEach olefinic D and A group symmetric with respect to the two relays.

^eEach *exo* olefinic D or A group disposed asymmetrically with respect to the long axis of the bridge.

Tethered Fe complexes

For the series $\mathbf{2}(m)$, $m = 2-4$, T_{if} values were obtained from optical electron-transfer data and r_{DA} values were estimated as well [27]. For these systems, diabatic r_{DA} values based on Eq. 83 are within $\sim 0.01 \text{ \AA}$ of r_{FcFc} values. Results are summarized in Table 5. In spite of the homologous character of the series, the sequence of T_{if} and r_{DA} values does not yield a simple trend with m or r_{DA} . Detailed orbital calculations did not give a good quantitative account of T_{if} (values of 60 cm^{-1} , 46 cm^{-1} , and 0.4 cm^{-1} were obtained for $m = 2, 3$, and 4 , respectively), but the analysis of the calculations did yield some useful qualitative insights [27]. Specifically, comparison of T_{if} values for the full $m = 2$ and $m = 4$ systems and those in which the $(\text{CH}_2)_m$ tethers were excised revealed significant destructive interference between pathways involving ts coupling of adjacent pyridyl groups (pairs which are tethered in the full ligand) and th pathways involving the tethers. In contrast, for $m = 3$, removal of the tether left T_{if} unchanged, suggesting no th coupling. The results for $m = 2$ and 4 are qualitatively consistent with the simple parity rule, for which the ts pathway and the th pathways involving an odd number of CC bonds would be expected to have opposite phases [27]. This pattern has been found in calculations for cases of both *gauche* (the present case) and *trans* staggered tether conformations. The fact that th coupling is almost entirely “quenched” in the $m = 3$ case (in contrast to expectations of constructive interference) has been attributed to the highly constricted conformation of the $m = 3$ tethers (intermediate between *gauche* and *cis* limits) [27].

Coupling of monomer units in the bacterial photosynthetic reaction center

The availability of X-ray crystal-structure data for the bacterial photosynthetic reaction center (RC) has stimulated a wide variety of theoretical and computational studies with the goal of helping to resolve the mechanistic details of the fast (3 ps) initial electron-transfer event from the photoexcited special pair (bacteriochlorophyll dimer P) to the bacteriopheophyll (H) residing 17 Å away (based on center-to-center separation). Convenient recent summaries of much of the relevant research are given in [152] and [153]. Among the major issues of interest are the intermediate role of the accessory bacteriochlorophyll (B) lying close to both P and H, and to understand the kinetic preference for one pathway, the so-called L-side branch involving the P–B_L–H_L triad, over another, the M-side branch involving the P–B_M–H_M triad, which superficially appears quasi-symmetry-equivalent to the L-branch. The relevant kinetics can be represented schematically as (see also Eq. 10),

where the dimer **P** is common to both branches. Early debates about the relative importance of a direct superexchange process governed by rate constant k_3 (in which $\text{P}^+\text{B}^-\text{H}$ plays the role of a virtual state) as opposed to a sequential process (with rate constants k_1 and k_2) involving a bona fide intermediate $\text{P}^+\text{B}^-\text{H}$ species, have

recently approached a consensus favoring the latter model, with the first step being the slower one (i.e., $k_2 > k_1 \gg k_3$) [78, 152, 153]. The daunting task of obtaining, from molecular-level computations, reliable estimates of the energy gaps for modeling the rate constants continues to be a major challenge, especially when it comes to consistently balancing the energetics of the P,B, and H chromophores and of the protein medium [112e, 154, 155].

While the accurate evaluation of electronic coupling (T_{if}) among the different chromophores is also very difficult, and is undoubtedly sensitive to uncertainties in the experimental atomic coordinates, several studies (based either on *ab initio* electronic structure calculations [112e, 154] or a quantum dynamical simulation with parameters adjusted to reproduce experimental kinetic data [156]) have yielded results in general accord with each other and also with earlier estimates inferred from experimental kinetic data based on a non-adiabatic model [152, 153]. The results are summarized in Table 6, and show two clear trends in coupling magnitudes:

$$T_{if}(L) > T_{if}(M) \quad (105)$$

$$T_{if}(B^-H \rightarrow BH^-) > T_{if}(P^*B \rightarrow P^+B^-) \quad (106)$$

Table 6. Calculated T_{if} values linking the bacterial photosynthetic chromophores.

Branch ^a	Chromophore Pair in electron transfer process ^b	$ T_{if} $ (cm ⁻¹)		Experiment ^d
		Ab initio electronic structure calculation SCF ^d	Quantum dynamics calculation ^c CI ^e	
L-side	P*B → P ⁺ B ⁻	17	35	22
	B ⁻ H → BH	122	71	135
M-side	P*B → P ⁺ B	(~1) ^h	9	—
	B ⁻ H → BH ⁻	95	28	—

^aActive and inactive branches are denoted, respectively, L-side and M-side.

^bThe bacteriochlorophyll dimer (special pair), accessory bacteriochlorophyll, and bacteriopheophytin are denoted, respectively, as P,B, and H.

^c T_{if} values obtained from phenomenological analysis of experimental kinetic data based on quantum dynamics simulation [156].

^d T_{if} based on SCF calculations for appropriate states (neutral, excited singlet, or radical ion) of individual chromophores. The P^* state was represented as the 50:50 mixture of locally excited P states (P_L^* and P_M^*), constructed as two-configuration wavefunctions based on filled and virtual SCF orbitals of the separate P_L and P_M moieties [154].

^e T_{if} based on SAC-CI wavefunctions for the appropriate states (neutral, excited singlet, or radical ion) of the P,B, and H moieties [112c].

^f[153]. Similar values (26 and 51) were inferred [153] from the results presented in [152].

^gEstimated value for the $PB^*H \rightarrow PB^+H^-$ process, which involves the same lowest unoccupied orbitals (lumo) of the neutral B and H moieties as in the $P^+B^-H \rightarrow P^+BH^-$ process [157].

^hMagnitude uncertain because of near-cancellation of P_L^* and P_M^* contributions.

Thus, as far as electron coupling is concerned, the L-side is preferred to the M-side, and the first step in the sequence (Eq. 104) is the slower one; the trend is the same one exhibited by the overall rate-constant estimates [152, 153].

In the *ab initio* electronic-structure calculations, some attempt was made to assess the sensitivity of T_{if} magnitudes, by comparing results based on *in vacuo* chromophore pairs with those including nearby amino acid residues or crude representations of the extended environment, with point-charge or dielectric-continuum models. The results were found to be rather insensitive to such variations. Insensitivity of this type has been observed in previous model calculations. For example, in the case of the $\phi\text{H}/\text{Cl}$ charge-transfer system, *in vacuo* T_{if} values were found to change by $\leq 10\%$ when an aqueous medium was represented by a dielectric-continuum model, even though the solvation in this case caused a 50 % red shift in the vertical ET gap [30b]. In long-range superexchange coupling, solvent-dependent energy gaps (e.g., Δ in the McConnell model (Eq. 86) might be expected to cause appreciable variation in T_{if} for a given DBA system. In cases where a number of different types of pathways are superposed, however, such solvent sensitivity may be attenuated.

Calculation of activation parameters

As a final example, we summarize some results of a recent ambitious attempt to provide a comprehensive mechanistic account of long-range ET in a complex molecular solute in aqueous solution by exploiting molecular dynamics and electronic-structure techniques [36].

Reactive system

The DBA system, displayed in Figure 7, consists of a derivatized $[\text{Ru}(\text{bpy})_3]^{1+}$ donor group (where $\text{bpy} = 2,2$ -bipyridine), a $(\text{pro})_4$ bridge (where $\text{pro} = \text{proline}$ and the tetrapeptide is in a polyproline II helical conformation), and a $[\text{OC}(\text{NH}_3)_5]^{2+}$ acceptor group. The nominal redox process corresponds schematically to

where the excess electron localized on the bpy linked (by a carbonyl group) to the $(\text{pro})_4$ bridge reduces the Co^{3+} site. This system is of interest for detailed theoretical study because it is a member of a homologous series for which a large body of kinetic data exists [158].

Mechanistic issues

Of the mechanistic issues dealt with in the full study (including kinetic trade-offs between different Co^{2+} spin states in the reaction product and the role of solvent and conformational fluctuations of the DBA system), we focus here on the activation parameters and related nuclear tunneling and entropy effects which are crucial for establishing meaningful contact with the Arrhenius parameters obtained from the experimental rate data [158]. The theoretical analysis also led to new insights

Figure 7. Diagram of the electron-transfer system modeled by MD simulation in [36]. The peptide bridge contains four proline residues, the donor is a $\text{Ru}(\text{bpy})_3$ derivative (where bpy = 2,2-bipyridine, with the transferring electron in the initial state largely localized on the bpy ligand linked to the bridge), and the acceptor is $-\text{OCO}(\text{NH}_3)_5$. (Figure 1 of [36], reprinted with permission, Copyright 1999, American Chemical Society).

regarding the extent to which different thermodynamic quantities are harmonic with respect to the electron transfer reaction coordinate [36].

Computational model

The structure and energetics of the nuclear coordinates were modeled with a Charmm-type force field for the DBA system (Figure 7) and a TIP3P potential for the approximately 1000 water molecules representing the solvent [36, 159]. Free-energy and enthalpic and entropic contributions were obtained from molecular dynamics (MD) simulations. Nuclear tunneling (Section 1.3.3) was included by discretized path-integral techniques (for the acceptor group, a major site of tunneling) and semiclassical techniques (for the remainder of the DBA system and for the solvent) [18, 94, 99]. T_{if} values were obtained from GMH (Eqs. 81 and 83) analysis of the results of INDO/s CI calculations [146] for the DBA system. A final crucial aspect of the model arises from the fact that the reaction has a finite driving force ($-\Delta G^\circ \neq 0$). Thus, in contrast to previous simulations, which dealt with symmetric exchange reactions ($\Delta G^\circ = 0$), the model Hamiltonian for the final state of the ET process (Eq. 107) was adjusted with a constant offset, which, by construction, constrained the overall calculated ΔG° at room temperature to match experimental estimates based on redox reduction potentials and spectral data (a value of $\Delta G^\circ = -13.84$ kcal/mol was adopted, based on low-spin Co^{2+} [36]). The offset does not, of course, constrain the individual enthalpy (ΔH°) and entropy (ΔS°) terms; they are left to be determined by the detailed simulations. It is important to emphasize that, in spite of the large number of empirical parameters used to define the initial and final state Hamiltonians, they are all derived from basic structural and energetic data and in no sense are fitted to kinetic data.

Matching of phenomenological and theoretical rate constant models

The rate constant (k_{et}) was expressed in terms of the results of the computer simulations, for which a non-adiabatic transition-state theory (TST) model was used. Since the experimental results were analyzed in terms of a phenomenological Arrhenius model [158], we relate experiment (left-hand side) and theory (right-hand side) in terms of the following two equations. For the weakly temperature-dependent prefactor we have:

$$(k_B T/h) \exp(S^\ddagger/k_B) = (2\pi T_{if}^2/\hbar)(4\pi k_B T\lambda)^{-1/2} \exp(S^\ddagger/k_B) \quad (108)$$

and for the Boltzmann factor:

$$\exp(-E_a/k_B T) = \exp(-H^\ddagger/k_B T) \quad (109)$$

In Eq. 108, S^\ddagger is the “true” activation entropy, being defined as

$$S^\ddagger = -dG^\ddagger/dT, \quad (110)$$

where G^\ddagger is defined in Eq. 43. By contrast, $S^{\ddagger'}$ is a “pseudo” entropy of activation, which includes the contribution from the non-adiabatic prefactor of Eq. 108 in addition to the quantity S^\ddagger defined in Eq. 110. Thus, in order to infer the value of T_{if} from the experimental data ($S^{\ddagger'}$), one must know the value of S^\ddagger , (not directly available from the data of [158]). In Eq. 109, E_a is the Arrhenius activation energy and H^\ddagger is given by

$$H^\ddagger = G^\ddagger + TS^\ddagger \quad (111)$$

Relationship between activation and net thermodynamic quantities

It is well known from Marcus theory that for diabatic free energies that are harmonic with respect to the reaction coordinate, G^\ddagger is a quadratic function of ΔG° (Eq. 27) [8, 9]. This result may be extended to H and S and is represented as follows [36, 93]:

$$X^\ddagger = (1 + \alpha)(\Delta X^0/2) + (1 - \alpha^2)(\lambda_X/4) \quad (112)$$

where $X \equiv G, H$, or S ,

$$\begin{aligned} \lambda_G &\equiv \lambda \\ \lambda_S &= -d\lambda/dT \\ \lambda_H &= \lambda + T\lambda_S \end{aligned} \quad (113)$$

and where

$$\alpha \equiv \Delta G^\circ/\lambda \quad (114)$$

is a relative measure of the driving force (the reorganizational entropy, λ_S , should not be confused with the solvent reorganization free energy, λ_s , introduced in Section 1.3.4 and also included in Table 7). Thus, in the harmonic regime, a knowledge of ΔX° (and also λ_X) directly yields an estimate of X^\ddagger . In the case of reaction 107, ΔS° is not known experimentally.

Results of calculations

Room temperature simulations at the classical level yielded values of all ΔX° and X^\ddagger quantities. Quantal results for G^\ddagger were also obtained from path integral simulations (in conjunction with Eq. 41) or semiclassical results based on spectral densities from the classical simulations [36]. The calculated classical G^\ddagger and λ values and the ΔG° value were found to conform well to Eq. 112, and $G_i(\eta)$ and $G_f(\eta)$ functions were close to parabolic in form. Due to systematic deficiencies in the aqueous solvent model (a nonpolarizable force field and finite Coulombic cut-off, ca. 10 Å), corrections to λ were made on the basis of reference dielectric continuum models, and then G^\ddagger was corrected accordingly on the basis of Eq. 112.

The calculations yield S^\ddagger and ΔS° values of appreciable magnitude, +18 eu: (cal mol⁻¹ K⁻¹) and +10 eu, respectively, and in contrast to the free energies, calculated S and H quantities depart substantially from the quadratic relationship given by Eq. 112. In the case of small α and also small λ_S , one expects, from Eq. 112, the value of $S^\ddagger/\Delta S^\circ$ to be approximately 0.5, whereas the calculations yield a ratio of approximately 2 (the distinction is pronounced even when the sizable estimated statistical uncertainties (± 5 eu) in the calculated entropies is taken account of). For this result to be compatible with Eq. 112, it would require a sizable positive value of λ_S , but in fact the simulation results indicated $\lambda_S \approx 0$. Thus, for reaction 107, as represented by the simulation and model molecular Hamiltonian [36], we infer that near room temperature the separate entropy and enthalpy quantities are not well accounted for by a harmonic model, whereas, due to compensating effects, harmonic behavior is recovered when they are combined in the free-energy quantities.

The final results, including the corrections noted above and the quantal tunneling suppression of the activation barrier (~ 2 kcal/mol, of which more than 50 % comes from solvent modes), are summarized in Table 7. (We note that nuclear tunneling is expected to make only a minor, negative, contribution to S^\ddagger [160]).

Comparison with experiment

With the data of Table 7 in hand, one may now make quantitative contact with experiment in terms of Eqs. 108 and 109. The experimental $S^{\ddagger'}$ value together with the calculated S^\ddagger value and Eq. 108 yields an estimate of T_{if} (0.1–2 cm⁻¹) that is close to the calculated range (0.5–5 cm⁻¹). Given the estimated uncertainties, the experimental (E_a) and calculated (H^\ddagger) activation energies are seen to be in reasonable accord as well. The primary results are summarized in Table 8.

The preceding analysis indicates the great importance of knowing S^\ddagger when it comes to unraveling the contributions to $S^{\ddagger'}$ from an Arrhenius analysis (failure to distinguish between the $S^{\ddagger'}$ and S^\ddagger values in Table 8 amounts to an error of a factor of approximately 20 in the T_{if} magnitude), and also offers an example in which

Table 7. Calculated thermodynamic quantities for the $\{\text{Ru}(\text{bpy})_2(\text{bpy}')(\text{pro})_4[\text{OCO}(\text{NH}_3)_5]\}^{3+}$ electron-transfer system^{a,b}.

G^\ddagger (kcal/mol)	5.7 ± 0.1
H^\ddagger (kcal/mol)	11.2 ± 1.5
S^\ddagger (eu) ^c	18.3 ± 5
ΔG° (kcal/mol)	$(-13.8)^d$
ΔS° (eu) ^c	10 ± 5
ΔH° (kcal/mol)	-10.8 ± 1.5
λ (kcal/mol)	
total	55 ± 0.1
solvent (λ_s)	39 ± 0.1
α^e	-0.25

^aThe full DBA structure is displayed in Figure 7. The electron transfer process corresponds nominally to the reduction of Co^{3+} by an electron localized on the bpy' ligand attached (by a carbonyl substituent) to the $(\text{pro})_4$ bridge; this leads to the low-spin (doublet) Co^{2+} final state. The G^\ddagger , H^\ddagger , and λ values were corrected for systematic limitations of the solvent model (as described in detail in [36]), and G^\ddagger and H^\ddagger include contributions from quantal tunneling.

^bAll results are taken from [36].

^ceu = cal mol⁻¹ K⁻¹.

^dConstrained by a constant offset in the final-state Hamiltonian (Section 1.5.2).

^e $\alpha \equiv \Delta G^\circ / \lambda$.

Table 8. Experimental vs calculated activation parameters^a.

Experiment ^b	Calculation ^c
$S^\ddagger = 5.5 \pm 0.8$ eu	$S^\ddagger = 18.3 \pm 5$ eu
$E_a = 9.4 \pm 0.2$ kcal/mol	$H^\ddagger = 11.2 \pm 1.5$ kcal/mol
$ T_{if} = 0.1 \text{--} 2$ cm ⁻¹	$ T_{if} = 0.5 \text{--} 5$ cm ⁻¹

^aSee Eqs. 108 and 109.

^b[158].

^c[36].

even if ΔS° was available from experiment, it would not be a useful guide for estimating S^\ddagger (i.e., by Eq. 112).

1.6 Concluding Remarks

As a result of rapidly evolving and mutually reinforcing advances in theoretical, experimental, and computational techniques, enormous recent progress has been achieved in the quantitative mechanistic understanding of electron transfer (ET)

processes at the molecular level. A number of detailed examples of this progress were offered in Section 1.5, and showed two distinct ways in which theory may be tested by experiment: first, by appropriate comparisons of independent sets of experimental data for distinct, but interrelated properties, and, second, by comparison of experimental data with the results of theory obtained on the basis of detailed computational implementation.

The exploitation of a number of powerful quantal, semiclassical, and classical approaches (many of which are surveyed in the present chapter), makes it possible to give a satisfactory quantitative account of the crucial energetic and dynamic features controlling ET kinetics and to assemble them into overall ET rate constants for DBA aggregates of increasingly rich chemical complexity.

While progress abounds, key challenges remain for the future. At the technical level, aside from the need for across-the-board refinements and extensions of techniques for dealing with the individual mechanistic components (e.g., practical schemes for treating polarizable molecular-level response of the medium), it is essential to combine these components in a balanced, self-consistent manner when rate constants are formulated. This latter issue is especially important when it comes to interfacing detailed quantal and/or molecular-level treatments of crucial portions of "reactive sites" with "coarser-grained" treatments of peripheral regions of a reactive system. Another challenge, at the quantal level, is to ascertain the limitations of purely electronic models (e.g., of the superexchange type) more systematically and to identify situations where vibronic factors are essential.

A key focus for the future is to broaden the chemical context of electron-transfer processes by addressing the full range of coherent and incoherent electron transport phenomena occurring in condensed phases, by extending kinetic models to accommodate electron transfer occurring together with chemical bonding rearrangements, and by exploiting the many interrelationships between ET and other manifestations of donor/acceptor interactions.

Acknowledgments

This work was carried out at Brookhaven National Laboratory under contract DE-AC02-98CH10886 with the U.S. Department of Energy and supported by its Division of Chemical Sciences, Office of Basic Energy Sciences. Thanks are also due to Norman Sutin for a number of helpful comments.

2 Adiabatic versus Non-Adiabatic Electron Transfer

Hitoshi Sumi

2.1 Adiabatic versus Static Coupling Scheme

It is assumed throughout this chapter that the relative positions of the donor and acceptor molecules between which an electron is transferred are fixed either within a large molecule or by a molecular bridge in solvents. In this situation, electron-transfer (ET) reactions are governed by first-order kinetics. In second-order reactions [1], the donor and acceptor first diffuse to mutually appropriate positions where the reaction takes place with a position-dependent rate constant. In that case, this is the rate constant discussed in the present article.

Integration signs without integration limits will often be used in this article. They are understood to be performed from $-\infty$ to ∞ unless it is explicitly stated to be otherwise.

Electrons with mass m and atoms with mass M that can move freely have average velocities $(3k_{\text{B}}T/m)^{1/2}$ and $(3k_{\text{B}}T/M)^{1/2}$, respectively, at temperature T , where k_{B} is the Boltzmann constant. Therefore, electrons move much faster than atoms, since the ratio of the electron speed to the atom speed, ca. $(M/m)^{1/2}$, is much larger than unity. In this situation, an approximation is justified that, an electron can be regarded to move in a potential of, atoms stopping at certain positions. This is called the adiabatic approximation, because the energy recoil of the atoms that is caused by the interaction with the electron is neglected. The eigenenergy of the electron given as a function of coordinates of the atoms, supplemented by the distortion energy for atomic displacement, is called the adiabatic potential. Since this approximation was first devised by Born and Oppenheimer [2], it is named after them.

In electron-transfer reactions occurring in condensed matter, this approximation is not always justified, since the electrons and atoms participating in the transfer are not free. Electron motion is confined only to that occurring between a donor and an acceptor molecule, and atoms can vibrate only around their equilibrium positions. In the transition state of an electron transfer reaction, an electron stays at either the donor or the acceptor for a time of about \hbar/J where J represents the interaction

energy for electron transfer between them, called the transfer integral hereafter, and \hbar represents the Planck constant divided by 2π . When the average energy quantum of vibrations of the atoms around their equilibrium positions is written as $\hbar\bar{\omega}$, the average period of their vibrations is given by $2\pi/\bar{\omega}$. In order for the adiabatic approximation to be justified in this situation, \hbar/J must be much smaller than $\hbar/(\hbar\bar{\omega})$, that is, J must be much larger than $\hbar\bar{\omega}$. The value of J is typically of the order of 100 cm^{-1} or less, while $\hbar\bar{\omega}$ varies from several tens cm^{-1} for protein-matrix vibrations [3] to about 3500 cm^{-1} for proton vibrations [4]. The adiabatic approximation is therefore not always applicable to ET reactions in condensed matter.

Let us consider, for simplicity, that an electron (with mass m) to be transferred interacts with atoms through a single reaction coordinate Q . To be more concrete, Q is a coordinate which passes through the atomic configuration relaxed at the reactant state and that at the product state in the multi-dimensional configuration-coordinate space for atomic displacement. Let us consider that atoms with mass M move along this reaction coordinate, and also that atoms at position Q on this reaction coordinate exert a potential $V(\mathbf{r}; Q)$ on the electron at position vector \mathbf{r} . The Hamiltonian for this system is given by

$$H = -\frac{\hbar^2}{2m}\Delta_{\mathbf{r}} - \frac{\hbar^2}{2M}\frac{\partial^2}{\partial Q^2} + V(\mathbf{r}; Q) + U(Q) \quad (1)$$

where $\Delta_{\mathbf{r}}$ represents the Laplacian operator with respect to \mathbf{r} , and $U(Q)$ represents the distortion energy for atomic displacement along the coordinate Q .

In the adiabatic approximation, the electron motion is diagonalized under the condition that the atoms are fixed at a value Q of the reaction coordinate, as a solution to a Schrödinger equation

$$\left[-\frac{\hbar^2}{2m}\Delta_{\mathbf{r}} + V(\mathbf{r}; Q) \right] \varphi(\mathbf{r}; Q) = E(Q)\varphi(\mathbf{r}; Q) \quad (2)$$

with an eigenfunction $\varphi(\mathbf{r}; Q)$ and an eigenenergy $E(Q)$, both of which depend on Q as a parameter. In the next step, the atoms are allowed to move on a potential $U(Q) + E(Q)$ supplemented by $E(Q)$, as a solution to a Schrödinger equation

$$\left[-\frac{\hbar^2}{2M}\frac{\partial^2}{\partial Q^2} + U(Q) + E(Q) \right] \chi(Q) = E\chi(Q) \quad (3)$$

with an eigenfunction $\chi(Q)$ and an eigenenergy E . Accordingly, the eigenfunction of H in Eq. 1 is approximated by a product of $\varphi(\mathbf{r}; Q)\chi(Q)$, and its eigenenergy by E .

$U(Q) + E(Q)$ is the adiabatic potential. It describes the total energy of the reaction system (composed of the electron and atoms) under the adiabatic condition that the atoms are fixed at a value Q of the reaction coordinate. In the typical example shown in Figure 1, it consists of a lower and an upper branch, arising from a pair of $E(Q)$ curves. The lower branch is a double well; the electron to be trans-

Figure 1. An example of a pair of adiabatic potentials with an avoided crossing at $Q = Q_c$ where the energy separation is $2J$. As the energy difference between them becomes much larger than J , each of them approaches one of the diabatic potentials $V_r(Q)$ and $V_p(Q)$ of Figure 2.

ferred is at the donor in the reactant-state well on the left-hand side, whose minimum is taken as the zero of the reaction coordinate Q . The electron is at the acceptor in the product-state well on the right-hand side, with a minimum at $Q \neq 0$, and the reaction system is in the transition state at the top of the barrier at $Q = Q_c$. The upper branch reaches a minimum at $Q = Q_c$, and crossing with the lower one is avoided. The energy separation between them at $Q = Q_c$ is $2J$.

This adiabatic eigenfunction $\phi(r; Q)\chi(Q)$ is not a rigorous eigenfunction of H , since

$$H\phi(r; Q)\chi(Q) = (E + H')\phi(r; Q)\chi(Q) \quad (4)$$

with

$$H'\phi(r; Q)\chi(Q) = -\frac{\hbar^2}{2M} \left[2\frac{\partial\phi(r; Q)}{\partial Q} \frac{d\chi(Q)}{dQ} + \frac{\partial^2\phi(r; Q)}{\partial Q^2} \chi(Q) \right] \quad (5)$$

In the adiabatic approximation, H' in Eq. 4 is neglected. H' is called the non-adiabaticity operator, and causes phenomena deviating from the adiabatic approximation such as nonradiative transitions between adiabatic states. The adiabatic-coupling scheme is a procedure for investigating such phenomena on the basis of H' .

This scheme is, however, not easy to pursue because H' of Eq. 5 is a differential operator with respect to Q . Moreover, the Q -dependence of H' is related to the highly anharmonic form of the adiabatic potential around the avoided-crossing point $Q = Q_c$ in Figure 1, since $\phi(r; Q)$ in Eq. 5 is an eigenfunction whose eigenenergy is given by the adiabatic potential at Q . They must be treated consistently with one another. Nevertheless, because of these difficulties, H' has often been approximated into simplified forms, not taking due account of its consistency with the highly anharmonic adiabatic potential. This can result in unpleasant situations [5], so that calculations based on H' , for example, those of nonradiative transition rates deviate very much from experimental observations.

To avoid such difficulties with H' , another scheme has been devised, where calculation of such quantities as nonradiative transition rates is approached from the

non-adiabatic limit. In this scheme, the static-coupling scheme [5], electronic states are defined by the diagonalization of a Hamiltonian for an electron which moves in a potential $V(\mathbf{r}; Q_0)$ produced by atoms at a value Q_0 of the reaction coordinate Q . It is convenient to choose Q_0 to be the Q value of zero at the bottom of the reactant well in Figure 1. Eigenstates $[\varphi_b(\mathbf{r})]$ in this scheme are solutions to a Schrödinger equation

$$\left[-\frac{\hbar^2}{2m} \Delta_r + V(\mathbf{r}; 0) \right] \varphi_b(\mathbf{r}) = E_b \varphi_b(\mathbf{r}) \quad (6)$$

with eigenenergy E_b , where $b = r$ for the reactant state with the electron localized at the donor and $b = p$ for the product state with the electron localized at the acceptor. Since both $\varphi_r(\mathbf{r})$ and $\varphi_p(\mathbf{r})$ are assumed to be nondegenerate, it can be taken as a real function. Since a part of $V(\mathbf{r}; 0)$ in $V(\mathbf{r}; Q)$ was incorporated in defining the electronic states, interaction between the electron and vibrational motions of atoms is caused by $V(\mathbf{r}; Q) - V(\mathbf{r}; 0)$. Here, two sets of phonon representations are introduced in association with the reactant and the product state $\varphi_r(\mathbf{r})$ and $\varphi_p(\mathbf{r})$ of the electron, as diagonalizing different Hamiltonians

$$H_b \equiv -\frac{\hbar^2}{2M} \frac{\partial^2}{\partial Q^2} + V_b(Q) \quad (7)$$

with

$$V_b(Q) \equiv U(Q) + \langle \varphi_b | [V(\mathbf{r}; Q) - V(\mathbf{r}; 0)] | \varphi_b \rangle + E_b \quad (8)$$

for $b = r$ or p , where $\langle \varphi_b | f(\mathbf{r}) | \varphi_b \rangle \equiv \int \varphi_b(\mathbf{r})^2 f(\mathbf{r}) d\mathbf{r}$. Let us confine ourselves to a subspace spanned by $\varphi_r(\mathbf{r})$ and $\varphi_p(\mathbf{r})$, assuming that their energy is well separated from other electronic states. Under this simplification, the Hamiltonian, H , of Eq. 1 can be rewritten, with the representation of Dirac's bra and ket vectors [6], into

$$H = H_r |\varphi_r\rangle \langle \varphi_r| + H_p |\varphi_p\rangle \langle \varphi_p| + J(Q) (|\varphi_p\rangle \langle \varphi_r| + |\varphi_r\rangle \langle \varphi_p|) \quad (9)$$

with

$$J(Q) \equiv \langle \varphi_p | [V(\mathbf{r}; Q) - V(\mathbf{r}; 0)] | \varphi_r \rangle \quad (10)$$

where $\langle \varphi_p | f(\mathbf{r}) | \varphi_r \rangle \equiv \int \varphi_p(\mathbf{r}) f(\mathbf{r}) \varphi_r(\mathbf{r}) d\mathbf{r}$ and $J(Q)$ is real, since both $\varphi_r(\mathbf{r})$ and $\varphi_p(\mathbf{r})$ are taken as real functions. The Hamiltonian, H , of Eq. 9 is the basis of the static coupling scheme, where we should note that $J(Q)$ which causes coupling between the electron states in Eq. 9 is not a differential operator but a simple real number, unlike in H' of Eq. 5 in the adiabatic coupling scheme. Both $V_r(Q)$ and $V_p(Q)$ are diabatic potentials, in contrast to the adiabatic potentials in the adiabatic approximation.

Figure 2 shows the diabatic potentials which give rise to the adiabatic potentials of Figure 1.

Figure 2. Diabatic potentials which give rise to the adiabatic potentials of Figure 1 in the adiabatic approximation.

The adiabatic potential $U(Q) + E(Q)$ in the adiabatic approximation is an eigenvalue of

$$V_r(Q)|\varphi_r\rangle\langle\varphi_r| + V_p(Q)|\varphi_p\rangle\langle\varphi_p| + J(Q)(|\varphi_p\rangle\langle\varphi_r| + |\varphi_r\rangle\langle\varphi_p|), \quad (11)$$

and $\varphi(r; Q)$ in Eq. 2 is an eigenstate of it. Of the two eigenenergies of the Hamiltonian of Eq. 11, the lower one represents the lower adiabatic potential in Figure 1 as a function of Q , and the upper one represents the upper adiabatic potential. At the avoided-crossing point between the two adiabatic potentials, $Q = Q_c$,

$$V_p(Q) = V_r(Q) \quad (12)$$

At this point, therefore, the upper and the lower adiabatic potentials are separated by

$$V_r(Q_c) \pm J, \quad \text{where } J \equiv |J(Q_c)| \quad (13)$$

with the eigenstates given by $\varphi(r) = [\varphi_r(r) \pm \varphi_p(r)]/\sqrt{2}$, where the reactant and the product state are equally mixed. Note that J in Figure 1 can be obtained from Eq. 13.

In the region of Q where the separation between $V_r(Q)$ and $V_p(Q)$ is much larger than $|J(Q)|$, the upper and the lower adiabatic potential, obtained by diagonalization of Eq. 11, merge into either $V_r(Q)$ or $V_p(Q)$, as indicated in Figure 1. At $Q = 0$ in Figure 1, $V_r(Q)$ and $V_p(Q)$ coincide exactly with the lower and the upper adiabatic potential, respectively, since $J(Q) = 0$ in Eq. 11. We assume hereafter that this region also covers the bottom of the product well in Figure 1. In this case, around the bottom of the reactant and the product well they are nearly equal to $V_r(Q)$ and $V_p(Q)$, respectively. The energy at the bottom of the reactant well was taken as the origin of the energy in Figure 1. Since the bottom was taken to be located also at the origin of coordinate Q , we should have

$$V_r(Q) \propto Q^2 \quad \text{in the vicinity of } Q = 0. \quad (14)$$

Around $Q = Q_c$, on the other hand, the adiabatic potentials given by Eq. 13 deviate markedly from both $V_r(Q)$ and $V_p(Q)$, which cross each other there as shown by Eq. 12. Adiabatic potentials approach either $V_r(Q)$ or $V_p(Q)$ in the limit of small J . This is a reason why both $V_r(Q)$ and $V_p(Q)$ are called diabatic potentials.

We have seen that the Hamiltonian in Eq. 4 for the adiabatic coupling scheme as well as that of Eq. 9 for the static coupling scheme are different representations of the same initial Hamiltonian of Eq. 1. Moreover, since the lower adiabatic potential was assumed to be nearly equal to $V_p(Q)$ at the bottom of the product well, both the initial and the final states of electron transfer are the same for the adiabatic and the static coupling scheme. These two features ensure that the two schemes are equivalent, as long as they are treated correctly. In fact, it has been shown, by explicit manipulation, that the adiabatic and the static coupling schemes give the same rate constant for electron transfer between donor and acceptor in the calculation of the lowest (i.e., second) order in the coupling strength J of Eq. 13 [5]. In this case, it is important to take due account of the consistency between the Q dependence of H' and the highly anharmonic form of the adiabatic potential around the avoided-crossing point in the adiabatic coupling scheme.

This condition for the adiabatic coupling scheme makes itself much more difficult to pursue than the static coupling scheme. In fact, reliable theories have been developed only on the basis of the static coupling scheme. Since the two approaches are equivalent, from this point on we consider only those based on static coupling. The rate constant for electron transfer between donor and acceptor becomes proportional to J^2 in the limit of small J , where the diabatic potentials in Figure 2 are most appropriate for describing the reaction. This limit is the non-adiabatic limit. The condition justifying this limit will be dealt with later. In the limit of large J , where the adiabatic potentials in Figure 1 are most appropriate for describing the reaction, the rate constant becomes independent of J , as will also be shown later. This limit is called the adiabatic limit.

The rate constant k_{FW} for forward electron transfer, that is, from donor to acceptor, is related to k_{BW} for reverse electron transfer, that is, from acceptor to donor, by the principle of chemical equilibrium. Specifically, they should satisfy

$$k_{FW}/k_{BW} = e^{-\beta\Delta G} \text{ (= Equilibrium constant).} \quad (15)$$

where ΔG represents the free energy of reaction, that is, the free energy at the product state (with an electron transferred to the acceptor), with the reactant state (with the electron staying at the donor) as the reference point. For the sake of simplicity, we will hereafter assume that the forward reaction is exothermic, with a negative ΔG . The rate constant for an endothermic reaction, with a positive ΔG , can be derived by Eq. 15 from k_{FW} for an exothermic reaction whose free energy of reaction is $-|\Delta G|$.

2.2 Non-Adiabatic Limit

2.2.1 Single-Mode Model

In the static coupling scheme, $J(Q)$ of Eq. 10 causes transitions of an electron from the donor to the acceptor. It works most effectively around $Q = Q_c$, where diabatic

potentials $V_r(Q)$ and $V_p(Q)$ cross each other, as shown in Figure 2. For the sake of simplicity, therefore, let us assume $J(Q) = J$ with J defined by Eq. 13, neglecting the Q dependence of $J(Q)$; this is called the Condon approximation. It is reasonable in the static coupling scheme, although risky in the adiabatic coupling scheme [5]. Thus, Eq. 9 can be approximated by

$$H = H_r|\varphi_r\rangle\langle\varphi_r| + H_p|\varphi_p\rangle\langle\varphi_p| + J(|\varphi_p\rangle\langle\varphi_r| + |\varphi_r\rangle\langle\varphi_p|) \quad (16)$$

Let us assume, moreover, that $V_r(Q)$ defined by Eq. 8 for $b = r$ is quadratic in the entire Q region, not only in Eq. 14, and also that $V_p(Q)$ for $b = p$ deviates from $V_r(Q)$ only by a linear function of Q . In this situation, it is convenient to express H_r in Eq. 7 for $b = r$ as

$$H_r = \frac{1}{2}\hbar\bar{\omega}P^2 + V_r(Q), \quad \text{with } V_r(Q) = \frac{1}{2}\hbar\bar{\omega}Q^2 \quad (17)$$

where $P \propto \hat{c}/\hat{c}Q$. In this model, the single-mode model, P and Q are a pair of conjugate operators of a single phonon mode, and they satisfy a commutation relation $[Q, P] = i$ with $[A, B] \equiv AB - BA$. In this case, $\hbar\bar{\omega}$ gives the energy quantum of this phonon mode. In reality, the reaction coordinate Q is a linear combination of various coordinates of phonons with various energy quanta, as explicitly shown later. Therefore, $\hbar\bar{\omega}$ should be regarded as an average energy quantum of all phonons contributing to Q . Even in this case, if all these phonons correspond to a single energy quantum, Q can still be regarded as a normal mode, since any linear combination of these still result in a normal mode.

Parallel to Eq. 17 for H_r , we express H_p in Eq. 7 for $b = p$ as

$$H_p = \frac{1}{2}\hbar\bar{\omega}P^2 + V_p(Q), \quad \text{with } V_p(Q) = \frac{1}{2}\hbar\bar{\omega}(Q - \sqrt{2\lambda/\hbar\bar{\omega}})^2 + \Delta G \quad (18)$$

where ΔG is the free energy of reaction in Eq. 15, and gives the energy at the bottom of $V_r(Q)$. According to Eq. 18, after reaction, atoms relax to a configuration described by $Q = \sqrt{2\lambda/\hbar\bar{\omega}}$ from that described by $Q = 0$. Since $V_p(0) - V_p(\sqrt{2\lambda/\hbar\bar{\omega}}) = \lambda$, this λ represents the energy of atomic reorganization after reaction, called the reorganization energy.

Diabatic potentials $V_r(Q)$ and $V_p(Q)$ cross each other at $Q = (\lambda + \Delta G)/(2\hbar\bar{\omega}\lambda)^{1/2}$, which gives Q_c in Figure 2. The energy of the crossing point measured from the bottom of $V_r(Q)$ is given by $V_r(Q_c) = (\lambda + \Delta G)^2/(4\lambda)$. This expression is called the Marcus relation, which gives the thermal activation energy ΔG^* for electron transfer in the non-adiabatic limit [7]. In the adiabatic limit, the thermal activation energy is reduced by J because of energy splitting by $2J$ at the crossing point, as shown in Figure 1. Since $(\lambda + \Delta G)^2/(4\lambda)$ in the non-adiabatic limit is a value of the lowest (i.e., zeroth) order in J , it seems reasonable to approximate the thermal activation energy for electron transfer by

$$\Delta G^* = (\lambda + \Delta G)^2/(4\lambda) - J \quad (19)$$

as long as the second term is a small correction of the right-hand side.

In the non-adiabatic limit, the rate constant for ET is determined in the lowest (i.e., the second) order in J . Therefore, the rate constant is given by Fermi's Golden Rule,

$$k = \frac{2\pi}{\hbar} J^2 \int \text{Tr} \delta(E - H_p) \delta(E - H_r) \rho_r dE \quad (20)$$

with

$$\rho_r \equiv \exp(-H_r/k_B T) / \text{Tr}[\exp(-H_r/k_B T)] \quad (21)$$

where Tr indicates that a trace is taken over all coupled phonons, and ρ_r is the density matrix for phonons in the reactant state. Since the phonon Hamiltonians H_r and H_p do not commute with each other, the two delta functions on the right-hand side of Eq. 20 cannot be united by integration over E .

In 1950, Huang and Rhys [8] were the first to obtain from Eq. 20 an analytic expression for the rate constant for electron transfer. They diagonalized H_r and H_p , respectively, by eigenstates $|m; r\rangle$ with eigenenergies $(m + \frac{1}{2})\hbar\bar{\omega}$ for $m = 0, 1, 2, \dots$ and eigenstates $|n; p\rangle$ with eigenenergies $(n + \frac{1}{2})\hbar\bar{\omega} + \Delta G$ for $n = 0, 1, 2, \dots$. Thus, Eq. 20 reduces to

$$k = \frac{2\pi}{\hbar} J^2 (1 - e^{-\beta\hbar\bar{\omega}}) \sum_{m,n} |\langle n; p | m; r \rangle|^2 \delta[-\Delta G - (n - m)\hbar\bar{\omega}] e^{-\beta m \hbar \bar{\omega}} \quad (22)$$

with $\beta \equiv 1/(k_B T)$. Here, $|\langle n; p | m; r \rangle|^2$ does not vanish for $m \neq n$ since $|m; r\rangle$ and $|n; p\rangle$ diagonalize the different Hamiltonians H_r and H_p , before and after the reorganization of atoms, respectively. When $n - m$ is written as ℓ , Eq. 22 can be rewritten as

$$k = (2\pi/\hbar) J^2 \sum_{\ell=-\infty}^{\infty} F_{\ell} \delta(-\Delta G - \ell \hbar \bar{\omega}) \quad (23)$$

with

$$F_{\ell} = \exp \left[\frac{\beta \ell \hbar \bar{\omega}}{2} - s \coth \left(\frac{\beta \hbar \bar{\omega}}{2} \right) \right] I_{\ell} \left(\frac{s}{\sinh(\beta \hbar \bar{\omega}/2)} \right) \quad (24)$$

for $s \equiv \lambda/(\hbar\bar{\omega})$, where $I_{\ell}(z)$ is a modified Bessel's function of the first kind of the ℓ -th order of argument z [9], and s represents a coupling constant called the Huang–Rhys factor. As shown in Appendix A, Eq. 23 with Eq. 24 can also be derived directly [10].

The right-hand side of Eq. 23 vanishes unless $\Delta G/(\hbar\bar{\omega})$ is an integer. This inconvenience arises from our initial assumption that the reaction coordinate Q constitutes a single normal mode with the energy quantum $\hbar\bar{\omega}$. In reality, Q should be composed of various normal modes of phonons with various energy quanta.

Keeping this in mind, we utilize the fact that $I_\ell(z) [= I_{-\ell}(z)]$ for an integer ℓ can be extended smoothly to $I_\nu(z)$ for a non-integral number ν , and we are led to the Huang–Rhys formula [8]

$$k = \frac{2\pi J^2}{\hbar^2 \bar{\omega}} \exp \left[-\frac{\beta \Delta G}{2} - s \coth \left(\frac{\beta \hbar \bar{\omega}}{2} \right) \right] I_{|\Delta G / \hbar \bar{\omega}|} \left(\frac{s}{\sinh(\beta \hbar \bar{\omega} / 2)} \right) \quad (25)$$

This formula is applicable to both exothermic reactions, with $\Delta G < 0$, and endothermic ones, with $\Delta G > 0$. In fact, the rate constant for reverse electron transfer, from acceptor to donor, k_{BW} , can be obtained by simply replacing ΔG with $-\Delta G$ in Eq. 25. It can easily be checked that they obey the principle of chemical equilibrium in Eq. 15. A special case of Eq. 25, for $\Delta G = 0$, was obtained in conjunction with hopping rates of small polarons on a deformable lattice [11].

2.2.2 Atom-Tunneling Regime

$I_\nu(z)$ can be approximated by $(z/2)^{|\nu|} / \Gamma(|\nu| + 1)$ when $z/2 \ll (|\nu| + 1)^{1/2}$, where $\Gamma(x)$ represents the gamma function of argument x [9]. Accordingly, Eq. 25 reduces to

$$k \approx (2\pi/\hbar) J_{\text{eff}}^2 / \hbar \bar{\omega} \quad (26)$$

with

$$J_{\text{eff}}^2 = J^2 \exp \left[-s \coth \left(\frac{\beta \hbar \bar{\omega}}{2} \right) \right] \frac{[s(\bar{n} + 1)]^{|\Delta G| / \hbar \bar{\omega}}}{\Gamma(1 + |\Delta G| / \hbar \bar{\omega})} \quad (27)$$

when

$$\frac{1}{2} s / \sinh(\beta \hbar \bar{\omega} / 2) \ll (1 + |\Delta G| / \hbar \bar{\omega})^{1/2}, \quad (28)$$

where $\bar{n} \equiv 1/(e^{\beta \hbar \bar{\omega}} - 1)$ represents the Planck distribution function of phonons. Eq. 27 is applicable only to exothermic reactions with $\Delta G < 0$.

The rate constant for ET can mathematically be regarded as the optical spectrum of a localized electron in the limit where the photon energy to be absorbed or emitted approaches zero. From the theory of radiative transitions [10, 12] and $\Gamma(\ell + 1) = \ell!$ for a positive integer ℓ , we see that the factor multiplied to J^2 on the right-hand side of Eq. 27 represents the thermally renormalized value of the Franck–Condon factor [i.e., the squared overlap integral between the lowest phonon state in $V_r(Q)$ and the $(|\Delta G|/\hbar \bar{\omega})$ -th one in $V_p(Q)$] for ET. The renormalization manifests itself in the Debye–Waller factor $\exp[-s \coth(\beta \hbar \bar{\omega} / 2)]$, smaller than e^{-s} , which appears also in neutron or X-ray scattering [12a]. Therefore, J_{eff} in Eq. 27 represents the effective matrix element for electron tunneling from the lowest phonon state in the reactant well with simultaneous emission of $(|\Delta G|/\hbar \bar{\omega})$ phonons,

Figure 3. Tunneling of atoms from the reactant-state potential $V_r(Q)$ to the product-state potential $V_p(Q)$ accompanied by emission of $(|\Delta G|/\hbar\bar{\omega})$ phonons.

shown in Fig. 3. In the rate constant for reverse electron transfer, in contrast, $(\bar{n} + 1)^{|\Delta G|/\hbar\bar{\omega}}$ in J_{eff}^2 is changed to $\bar{n}^{|\Delta G|/\hbar\bar{\omega}}$, since electron tunneling accompanies absorption of $(|\Delta G|/\hbar\bar{\omega})$ phonons. The last factor, $1/\hbar\bar{\omega}$, on the right-hand side of Eq. 26 represents the average density of final phonon states in ET. These features indicate that in this regime, ET (i.e., electron tunneling) from the donor to the acceptor is accompanied by simultaneous tunneling of atoms from the lowest phonon state in the reactant well around $Q = 0$ [Eq. 17] to the product well around $Q = \sqrt{2}s$ [Eq. 18], as shown schematically in Figure 3.

The condition of Eq. 28 for this atom-tunneling regime is definitely satisfied at low temperatures of $k_B T \ll \hbar\bar{\omega}$, irrespective of the magnitude of s and $|\Delta G|/\hbar\bar{\omega}$. Then the rate constant k of Eq. 26 becomes nearly independent of temperature, approaching $(2\pi/\hbar^2\bar{\omega})J^2 e^{-s|\Delta G|/\hbar\bar{\omega}}/\Gamma(1 + |\Delta G|/\hbar\bar{\omega})$. A typical example of this behavior is the electron transfer from cytochrome c to the oxidized special pair in the reaction center for photosynthesis at temperatures below ca. 60 K [13] (Figure 4).

The condition Eq. 28 is also satisfied for large $|\Delta G|/\hbar\bar{\omega} \gg 1$ where $\Delta G < 0$, as long as s is not much larger than unity in a temperature region of $k_B T \lesssim \hbar\bar{\omega}$. In this case, Stirling's formula $\Gamma(A + 1) \approx (A/e)^A$ for $A = |\Delta G|/\bar{\omega}$ enables us to rewrite Eq. 26 as

Figure 4. Temperature dependence of the rate constant for electron transfer from cytochrome c to the oxidized special pair in the reaction center of photosynthesis [13, 14].

$$k \propto \exp[-\alpha|\Delta G|/(\hbar\bar{\omega})], \quad (29)$$

with

$$\alpha = \log \left[\frac{|\Delta G|}{e s \hbar \bar{\omega}} (1 - e^{-\beta \hbar \bar{\omega}}) \right], \quad (30)$$

where α has a magnitude of the order of unity. According to Eq. 29, $\log k$ is an approximately linear function of $|\Delta G|/(\hbar\bar{\omega})$, with a slope of order unity, nearly independent of temperature. This relation is called the energy-gap law for a large gap of $|\Delta G|$. A typical example is nonradiative transitions of an electron between multiplet levels in rare-earth and alkaline-earth elements [15], where the electron is so shielded in an inner shell of an atom that it interacts only weakly with vibrations of surrounding atoms as $s \lesssim 1$.

2.2.3 Semiclassical and Classical Regimes

Rewriting $\delta(-\Delta G - \hbar\bar{\omega})$ into $(2\pi\hbar)^{-1} \int \exp[i(\Delta G + \hbar\bar{\omega})t/\hbar] dt$ and utilizing the relation $\sum_{\lambda} I_{\lambda}(z) a^{\lambda} = \exp[z(a + a^{-1})/2]$ for $a = \exp(i\bar{\omega}t + \beta\hbar\bar{\omega}/2)$ [9], we can recast Eq. 23 as

$$k = \left(\frac{J}{\hbar}\right)^2 \int \exp \left[i \frac{\Delta G}{\hbar} t - s \coth \left(\frac{\beta \hbar \bar{\omega}}{2} \right) + s \frac{e^{i\bar{\omega}t + \beta \hbar \bar{\omega}/2} + e^{-i\bar{\omega}t - \beta \hbar \bar{\omega}/2}}{2 \sinh(\beta \hbar \bar{\omega}/2)} \right] dt \quad (31)$$

This expression can also be obtained directly from Eq. 20 by the method of generating functions (Ref. [12] and Appendix B), as first done independently by Kubo and Lax [16].

Let us expand in t the exponent in the integrand on the right-hand side of Eq. 31, assuming that t satisfying $|\bar{\omega}t| \ll 1$ is most important in the integration over t . The reason for this assumption is explained below. Under this assumption, Eq. 31 reduces to

$$k \approx \left(\frac{J}{\hbar}\right)^2 \int \exp \left[i \frac{\lambda + \Delta G}{\hbar} t - \frac{s \bar{\omega}^2 t^2}{2} \coth \left(\frac{\beta \hbar \bar{\omega}}{2} \right) \right] dt \quad (32)$$

where λ represents the reorganization energy. Accordingly, the condition justifying this expansion turns out to be

$$s k_{\text{B}} T' \gg \hbar \bar{\omega}, \quad (33)$$

with

$$k_{\text{B}} T' \equiv \frac{\hbar \bar{\omega}}{2} \coth \left(\frac{\beta \hbar \bar{\omega}}{2} \right) = \begin{cases} k_{\text{B}} T, & \text{for } k_{\text{B}} T \gg \hbar \bar{\omega} \\ \frac{1}{2} \hbar \bar{\omega}, & \text{for } k_{\text{B}} T \ll \hbar \bar{\omega} \end{cases} \quad (34)$$

Here, the first equation in Eq. 34 can be expressed also as $k_{\text{B}}T' \equiv \hbar\bar{\omega}(\bar{n} + \frac{1}{2})$, with the use of the Planck distribution function \bar{n} in Eq. 27. Since $\hbar\bar{\omega}(\bar{n} + \frac{1}{2})$ is equal to the thermal average of the phonon Hamiltonian H_{r} in Eq. 17, the first equation in Eq. 34 represents

$$\langle V_{\text{r}}(Q) \rangle = k_{\text{B}}T'/2 \quad (34')$$

where $\langle f(Q) \rangle$ represents the thermal average of $f(Q)$ with respect to Q . Since $V_{\text{r}}(Q) \propto Q^2$, we see that T' represents an effective temperature measured by the average amplitude of fluctuations of the reaction coordinate Q . As noted in the last equation of Eq. 34, it approaches real temperature T at high temperatures of $k_{\text{B}}T \gg \hbar\bar{\omega}$, where Eq. 34' reduces to the equipartition law of energy in classical statistical mechanics. At low temperatures of $k_{\text{B}}T \ll \hbar\bar{\omega}$, on the other hand, T' approaches a nonvanishing value reflecting the zero-point vibration of Q , given by the last equation of Eq. 34.

Integration over t of the right-hand side of Eq. 32 is easy, and gives

$$k \approx \frac{J^2}{\hbar} \left(\frac{\pi}{\lambda k_{\text{B}}T'} \right)^{1/2} \exp\left(-\frac{\Delta G^*}{k_{\text{B}}T'}\right) \quad (35)$$

with ΔG^* of Eq. 19, where J on the right-hand side can be neglected in the present calculation which is lowest (i.e., second) order in J in the non-adiabatic limit. The regime giving the rate constant of Eq. 35 is called the semiclassical regime, realized under the condition of Eq. 33. As long as the Huang–Rhys factor s is much larger than unity, this condition is satisfied at any temperature. At low temperatures of $k_{\text{B}}T \ll \hbar\bar{\omega}$, the rate constant k of Eq. 35 becomes nearly independent of temperature. This behavior reflects that of the atom-tunneling regime, since its condition of Eq. 28 is satisfied at low temperatures irrespective of whether the condition of Eq. 33 for the semiclassical regime is satisfied or not, as pointed out in the previous subsection. At high temperatures of $k_{\text{B}}T \gg \hbar\bar{\omega}$, where T' approaches T , on the other hand, the condition of Eq. 33 is always satisfied, as long as s is not much smaller than unity. In this case, k of Eq. 35 shows thermally activated temperature dependence with activation energy ΔG^* , and the semiclassical regime reduces to the classical one. In the classical regime, atoms move classically without tunneling, although the transferred electron always moves quantum-mechanically.

In Eq. 35, the exponential factor on the right-hand side plays a dominant role in determining the magnitude of k . Two of the cases shown in Figure 5 give the same ΔG^* . In the semiclassical regime, therefore, the magnitude of the rate constant k should be similar for these two cases. The case where $-\Delta G < \lambda$ is the normal region, where k increases with an increase in the driving potential ($-\Delta G$) for chemical reaction due to a decrease in ΔG^* . This behavior follows common chemical intuition. However, for the inverted region, that is, where $-\Delta G > \lambda$, k decreases inversely with an increase in the driving potential ($-\Delta G$) because of an accompanying increase in ΔG^* . Accordingly, k reaches a maximum at the boundary between the two regions, at $-\Delta G \approx \lambda$. The existence of these two regions was first predicted by

Figure 5. Relative arrangement of diabatic potentials $V_r(Q)$ and $V_p(Q)$ for the reactant and product states, respectively, in the normal case for $-\Delta G < \lambda$, and the inverted case for $-\Delta G > \lambda$.

Marcus [17], and was confirmed experimentally by Miller and his collaborators [18], but only 24 years after its prediction. Additional aspects of the inverted region will be discussed in Section 2.5.1 which focuses on the different roles played by solvent and intrasolute modes of phonons.

The atom-tunneling regime under the condition of Eq. 28 always appears at low temperatures, $k_B T \ll \hbar\bar{\omega}$, irrespective of the magnitude of s . Accordingly, the rate constant k for electron transfer becomes nearly temperature-independent at low temperatures, whereas thermal activation occurs at high temperatures, $k_B T \gg \hbar\bar{\omega}$, as long as s is not much smaller than unity. A typical example of such a change in the temperature dependence of the rate constant can be found in the electron transfer from cytochrome c to the oxidized special pair in the reaction center for photosynthesis at ca. 90 K [13], as shown in Figure 4.

Integration variable t in Eq. 31 gives a measure of the time needed for an electron to make a transition from the donor to the acceptor in the phonon field. In the semiclassical approximation under the condition of Eq. 33, the time region of $|\bar{\omega}t| \ll 1$, that is, $|t| \ll 1/\bar{\omega}$, is most important in the integration in Eq. 31. Since $1/\bar{\omega}$ gives a measure of the vibration period of atoms, this means that the electron transition takes place in a time period much shorter than the vibration period, that is, it takes place while the atomic positions can be regarded as fixed during vibration. In this situation, it is said that the transition obeys the Franck–Condon principle, which was found empirically during the study of optical spectra of molecules in condensed matter [19]. We have seen that this principle can be justified by the condition of Eq. 33 for the semiclassical approximation [12, 16b, 20].

According to the Franck–Condon principle, electron transition from donor to acceptor takes place while the atomic positions can be regarded as fixed on the reaction coordinate Q . This means that it takes place at the crossing point between the diabatic potentials $V_r(Q)$ and $V_p(Q)$ for the reactant and product states, respectively, because energy conservation is satisfied only at that point under this principle. This situation can be formulated by

$$k \approx \frac{2\pi}{\hbar} J^2 \frac{\int \delta[V_p(Q) - V_r(Q)] \exp[-V_r(Q)/k_B T'] dQ}{\int \exp[-V_r(Q)/k_B T'] dQ} \quad (36)$$

where the weighting factor, $\exp[-V_r(Q)/k_B T']$, for the thermal average in Q , is justified by Eq. 34' since $V_r(Q) \propto Q^2$. Inserting $V_r(Q)$ and $V_p(Q)$ of Eqs. 17 and 18, we can see that k of Eq. 36 reproduces k of Eq. 35. However, Eq. 36 is considered to be more general than Eq. 35 in the semiclassical regime, since it allows that both $V_r(Q)$ and $V_p(Q)$ can have more general forms than those of Eqs. 17 and 18.

2.2.4 Multimode Model

Since the phonon energy quantum $\hbar\bar{\omega}$ does not explicitly appear in both Eqs. 35 and 36, these formulas for the rate constant in the semiclassical regime should be derived without the single-mode model being relied on. That is, we should not neglect that various phonon modes contributing to the reaction coordinate Q have, in reality, various energy quanta. In this case, the phonon Hamiltonian in the reactant state (where the electron to be transferred is at the donor) consists of various normal modes,

$$H_r = \frac{1}{2} \sum_j \hbar\omega_j (p_j^2 + q_j^2) \quad (37)$$

where p_j and q_j respectively represent the momentum and the coordinate operator of the j th normal mode with the energy quantum $\hbar\omega_j$, satisfying the commutation relation $[q_j, p_{j'}] = i\delta_{j,j'}$. Similarly, the phonon Hamiltonian in the product state (where the electron has been transferred to the acceptor) is written in a form generalizing Eq. 18, as

$$H_p = \frac{1}{2} \sum_j \hbar\omega_j [p_j^2 + (q_j - \sqrt{2s_j})^2] + \Delta G \quad (38)$$

with the Huang–Rhys factor s_j for the j th mode. The contribution to the reorganization energy from the j th mode and the total reorganization energy are given respectively by

$$\lambda_j = s_j \hbar\omega_j \quad \text{and} \quad \lambda = \sum_j \lambda_j \quad (39)$$

The reaction coordinate Q is defined as describing the difference between H_r and H_p , as

$$H_r - H_p = Q - (\lambda + \Delta G) \quad (40)$$

In this definition, Q has energy dimensions, giving the energy difference between the diabatic potentials for the reactant and the product states, while Q in Eqs. 17 and 18 was defined to be dimensionless. Inserting Eqs. 38 and 39 into Eq. 40, we get

$$Q = \sum_j (2\hbar\omega_j \lambda_j)^{1/2} q_j \quad (41)$$

The diabatic potential for the reactant state is given by the smallest value of $\sum_j \hbar \omega_j q_j^2 / 2$ under the condition of Eq. 41, as a function $V_r(Q)$ of the reaction coordinate Q . Since the potential for the product state differs from $V_r(Q)$ by only $(-Q + \lambda + \Delta G)$ from Eq. 40, it can also be given by a function $V_p(Q)$ of Q . Their explicit expressions are

$$V_r(Q) = \frac{Q^2}{4\lambda} \quad \text{and} \quad V_p(Q) = \frac{(Q - 2\lambda)^2}{4\lambda} + \Delta G \quad (42)$$

They cross each other at $Q = \lambda + \Delta G (= Q_c)$. We can also show that $V_r(Q_c)$ equal to $(\lambda + \Delta G)^2 / (4\lambda)$ agrees exactly with the smallest energy of $\sum_j \hbar \omega_j q_j^2 / 2$ under the condition of $Q = Q_c$, in agreement also with the right-hand side of Eq. 19 where J can be neglected in the present non-adiabatic limit. This means that the crossing point $Q = Q_c$ located on the reaction coordinate Q is really a saddle point on the crossing surface $Q = Q_c$ between the diabatic potentials for the reactant and the product states in the multidimensional coordinate space spanned by a number of q_j . Since Q is defined by Eq. 41, it in general does not correspond to a normal mode of the phonons, but is very convenient for describing the reaction, that is, as the reaction coordinate. In spectroscopy, the same coordinate is called in terms of the interaction mode [12b].

When Eq. 36 is extended to multimodes, the rate constant in the semiclassical approximation is given by

$$k \approx \frac{2\pi}{\hbar} J^2 \frac{\prod_j (\int dq_j \exp[-q_j^2 / \coth(\beta \hbar \omega_j / 2)]) \delta(Q - Q_c)}{\prod_j [\pi \coth(\beta \hbar \omega_j / 2)]^{1/2}} \quad (43)$$

The numerator on the right-hand side can be integrated with the use of $\delta(Q - Q_c) = (2\pi\hbar)^{-1} \int \exp[i(Q_c - Q)t/\hbar] dt$ for Q of Eq. 41. Finally, integrating over t , we can, as expected, reach the same expression for k as in Eq. 35, when we redefine T' there by

$$k_B T' = (2\lambda)^{-1} \sum_j \lambda_j \hbar \omega_j \coth(\beta \hbar \omega_j / 2) \quad (44)$$

This is a straightforward generalization of Eq. 34 in the multimode model, being an average of $\hbar \omega_j \coth(\beta \hbar \omega_j / 2) / 2$, with weight λ_j , whose sum equals λ by Eq. 39.

2.3 Adiabatic Limit

2.3.1 Semiclassical Regime

The non-adiabatic limit is justified when the transfer integral J for electron transfer is sufficiently small. On the other hand, when J is large enough, we approach the

Figure 6. Relative arrangement of the upper and lower branches of adiabatic potentials in the normal and the inverted case, arising from the diabatic potentials in Figure 5.

adiabatic limit. The following two sections are devoted to discussing the change in the rate constant with an increase in J , that is, the change from the non-adiabatic to the adiabatic limit. It is, however, only in the semiclassical regime under the condition of Eq. 33 with Eqs. 44 or 34 that this change has been clarified fully. Therefore, we confine ourselves to this regime in these sections.

In the semiclassical regime, ET can take place only at fixed atomic positions. Therefore, electron transfer takes place only in the vicinity of $Q \approx Q_c$.

In the adiabatic limit, the reaction can be described by the adiabatic potentials which are composed of the upper and the lower branch and whose energy separation is given by $2J$ at $Q = Q_c$, as shown in Figure 1. The relative positions of the branches are quite different for the normal and the inverted cases: the positions of the diabatic potentials appropriate for the non-adiabatic limit, shown in Figure 5, change to those shown in Figure 6 in the adiabatic limit for both the normal and the inverted case. In the normal case, the reactant-state potential corresponds to the left-hand well in the lower branch of the adiabatic potential. In the inverted case, on the other hand, it corresponds to the upper branch, which consists of a single well.

Reflecting the thermal atomic vibrations, the reaction system fluctuates along the reaction coordinate Q in the reactant-state potential. This motion is described as $Q(t)$ as a function of time t . In the reactive trajectory, $Q(t)$ approaches $Q \approx Q_c$ from the bottom of the reactant-state potential. In the normal case, after $Q(t)$ reaches $Q \approx Q_c$ on the lower-branch adiabatic potential, it passes $Q \approx Q_c$, tracing this branch as it extends, and enters the product-state potential, as shown in Figure 6. Therefore, the rate constant for ET is given by the frequency per unit time with which $Q \approx Q_c$ is reached as a result of thermal fluctuations of the system in the reactant-state potential, that is, in the normal case, by

$$k = \nu \exp(-\Delta G^*/k_B T') \quad (45)$$

with the height ΔG^* of the barrier at $Q \approx Q_c$ in the double-well adiabatic potential in Eq. 19 and the effective temperature T' determined by Eqs. 44 or 34. Here, ν represents an average frequency of phonons contributing to the reaction coordinate, and is called the attempt frequency. Its concrete value will be derived in the next subsection.

In the transition state theory for rates of chemical reactions [21], the value of ν was chosen a priori at the thermal frequency $k_B T/h$ with Planck's constant h , on the

assumption that $h\nu$ may be estimated by the average thermal energy $k_B T$ per phonon mode in the equipartition law of energy of classical statistical mechanics. This assumption was adopted without a theoretical formulation for the ν value. Its applicability seems questionable. In fact, classical statistical mechanics is justified only when $k_B T$ is much larger than the average energy quantum of phonons contributing to the reaction coordinate. Therefore, to be selfconsistent, $k_B T/h$ must be much larger than the average frequency ν of these phonons.

In the inverted case, on the other hand, after $Q(t)$ reaches $Q \approx Q_c$ from the bottom of the reactant-state potential, which is now the upper-branch of the adiabatic potential, $Q(t)$ returns back to the bottom of the initial reactant-state potential along the upper branch, as shown in Figure 6. Accordingly, in the inverted case, the

$$(\text{preexponential factor of } k) \Rightarrow 0 \quad (46)$$

2.3.2 Attempt Frequency

In the single-mode model, where all the modes contributing to the reaction coordinate are regarded as having the same energy quantum $\hbar\bar{\omega}$, the attempt frequency ν in Eq. 45 should be given by $\bar{\omega}/(2\pi)$. In the multimode model which is more realistic than the single-mode model, the expression of ν is not self-evident, since various modes contribute to the reaction coordinate with different energy quanta. The attempt frequency ν represents the frequency per unit time with which the reaction coordinate $Q(t)$ passes through $Q = Q_c$ in the course of its thermal fluctuations from the bottom of the reactant-state potential. To obtain ν , potentials around $Q = Q_c$ can be approximated by those of the diabatic potentials $V_r(Q)$ and $V_p(Q)$ crossing at that point, as schematically shown in Figure 7.

The Hamiltonian for the reactant-state potential in the multimode model is given by Eq. 37. In the semiclassical regime, both the coordinate q_j and its conjugate momentum p_j of the j th mode for $j = 1, 2, 3, \dots$ in the Hamiltonian can be regarded not as operators but as c -numbers. In this situation, Q of Eq. 41, given by a linear combination of q_j values, is regarded as the initial value of $Q(t)$ at $t = 0$. The distribution of these q_j values is given by $C_j^{-1} \exp[-q_j^2/\coth(\beta\hbar\omega_j/2)]$ in the semiclassical regime, as shown in Section 2.2, where $\hbar\omega_j$ is the energy quantum of the j th

Figure 7. Crossing between the diabatic potentials $V_r(Q)$ and $V_p(Q)$ at $Q = Q_c$ in the normal case, and the time evolution of the reaction coordinate $Q(t)$ approaching the crossing point $Q = Q_c$ in the course of its thermal fluctuations in the reactant-state potential.

mode, and C_j is a normalization constant explicitly written in the denominator on the right-hand side of Eq. 43. The momentum p_j values should also contribute to the determination of the time evolution of $Q(t)$. Because of the symmetry between q_j and p_j in the Hamiltonian of Eq. 37, the distribution of the p_j values should have the same form as that of the q_j values. If the distribution of the latter is extended, the distribution function for a set of $\{p_j, q_j\}$ should be given by

$$\rho_r(\mathbf{p}, \mathbf{q}) = \prod_j \frac{\exp[-(p_j^2 + q_j^2)/\coth(\beta\hbar\omega_j/2)]}{\pi \coth(\beta\hbar\omega_j/2)} \quad (47)$$

where \mathbf{p} and \mathbf{q} are vectors whose j th components are given by p_j and q_j , respectively.

Equation 47 is the same as the Wigner distribution function [22] which is the semiclassical expression of the density matrix ρ_r of Eq. 21, as shown in Appendix B. In fact, adopting Eq. 47 for ρ_r in Eq. 20 for the rate constant k in the non-adiabatic limit, we can obtain Eq. 43 for k in the semiclassical regime directly from Eq. 20, as shown below. Hamiltonians H_r and H_p are approximated as commutable with one another in the semiclassical regime. In this situation, two delta functions in Eq. 20 can be united into a single delta function $\delta(Q - \lambda - \Delta G) [= \delta(Q - Q_c)]$ by integration over E with the use of Eq. 40. Then, with the trace operation in Eq. 20 regarded as integrations in q_j and p_j values, Eq. 43 is obtained, where p_j integrations have been performed, being canceled out by their normalization constants in the denominator, since Q does not depend on the p_j values.

Time evolution of q_j and p_j is regulated by the Hamiltonian H_r of Eq. 37. When they are written as $q_j(t)$ and $p_j(t)$, respectively, they satisfy a set of equations of motion

$$dq_j(t)/dt = \omega_j p_j(t) \quad \text{and} \quad dp_j(t)/dt = -\omega_j q_j(t) \quad (48)$$

This set of equations is the same for quantum and classical mechanics. Under the initial condition of $q_j(0) = q_j$ and $p_j(0) = p_j$, the solution to Eq. 48 is given by a set of

$$q_j(t) = q_j \cos(\omega_j t) + p_j \sin(\omega_j t) \quad (49)$$

and $p_j(t)$ which can be determined by the first equation in Eq. 48. Inserting this $q_j(t)$ for q_j on the right-hand side of Eq. 41, we obtain the expression of $Q(t)$ as

$$Q(t) = \sum_j \sqrt{2\hbar\omega_j\lambda_j} [q_j \cos(\omega_j t) + p_j \sin(\omega_j t)] \quad (50)$$

where q_j and p_j can take various values under the Wigner distribution function (Eq. 47). When a set of $\{p_j, q_j\}$ is adopted, it determines a time evolution of $Q(t)$ by Eq. 50. We denote by t_c the time at which $Q(t)$ thus determined crosses $Q = Q_c$ with a positive velocity from the left to the right in Figure 7. Then, since $Q(t)$ has an oscillatory-damping time dependence, we should obtain a series of t_c values. The

frequency (until t) with which $Q = Q_c$ is passed by $Q(t)$ with a positive velocity is given by the τ integration of $\delta(\tau - t_c)$ from zero to t . Since $Q(t)$ is a specific trajectory determined by a specific set of $\{p_j, q_j\}$, what we want to obtain is only the average value of the times, given by

$$N(t) = \int_0^t \langle \delta(\tau - t_c) \rangle_r d\tau \quad (51)$$

where $\langle \cdots \rangle_r$ represents the average in $\{p_j, q_j\}$ over the Wigner distribution function (Eq. 47).

In the adiabatic limit, the rate constant k in the normal case is given by the average frequency per unit time with which $Q = Q_c$ is passed with $\dot{Q}(t) > 0$, that is, by $dN(t)/dt$ of

$$k = \langle \delta(t - t_c) \rangle_r. \quad (52)$$

Although this expression of k seems to be time-dependent, it is not, because of ergodicity which is satisfied after the averaging of $\langle \cdots \rangle_r$ in thermal equilibrium. Although $t = t_c$ is satisfied by $Q(t) = Q_c$ with $\dot{Q}(t) > 0$, the condition of only $Q(t) = Q_c$ is realized twice as often as $t = t_c$, since both signs of $\dot{Q}(t)$ are counted. Therefore, Eq. 52 can be rewritten as

$$k = \frac{1}{2} \langle |\dot{Q}(t)| \delta[Q(t) - Q_c] \rangle_r = \frac{1}{2} \langle |\dot{Q}(t)| \rangle_r \langle \delta[Q(t) - Q_c] \rangle_r, \quad (53)$$

where the second equality is ensured since $Q(t)$ and $\dot{Q}(t)$ are statistically independent.

Here, it is convenient to introduce the distribution function of the reaction coordinate $\langle \delta(Q - x) \rangle_r$ and that of its velocity $\langle \delta(\dot{Q} - v) \rangle_r$ with $Q = Q(0)$ and $\dot{Q} = \dot{Q}(0)$. We can calculate them by rewriting, for example, $\delta(\dot{Q} - v)$ into $(2\pi)^{-1} \int \exp[i(\dot{Q} - v)t] dt$, and by integrating in q_j and p_j for $\langle \cdots \rangle_r$ and finally by that in t . The result is

$$F(x) = \langle \delta(Q - x) \rangle_r = \frac{1}{\sqrt{4\pi\lambda k_B T'}} \exp\left(-\frac{x^2}{4\lambda k_B T'}\right) \quad (54)$$

and

$$G(v) = \langle \delta(\dot{Q} - v) \rangle_r = \frac{1}{\sqrt{4\pi\bar{\omega}^2 \lambda k_B T'}} \exp\left(-\frac{v^2}{4\bar{\omega}^2 \lambda k_B T'}\right) \quad (55)$$

with

$$\bar{\omega}^2 \equiv \sum_j \omega_j^3 \lambda_j \coth\left(\frac{\beta \hbar \omega_j}{2}\right) / \sum_j \omega_j \lambda_j \coth\left(\frac{\beta \hbar \omega_j}{2}\right) \quad (56)$$

where T' represents the effective temperature determined by Eq. 44.

Both the $\langle \cdots \rangle_r$ entities on the right-hand side of Eq. 53 can be calculated at $t = 0$, without a change in the result, because of ergodicity. Especially, $\langle \delta[Q(t) - Q_c] \rangle_r$ equals $F(Q_c)$ and $\langle |\dot{Q}(t)| \rangle_r$ equals $\int |v| G(v) dv$. Performing this integration in v , we obtain k of Eq. 53 as

$$k = (\bar{\omega}/2\pi) \exp(-\Delta G^*/k_B T') \quad (57)$$

where $Q_c = \lambda + \Delta G$ was used for the crossing point Q_c in Figure 7. Thus, we see that the attempt frequency ν in Eq. 45 is given by $\bar{\omega}/(2\pi)$ where $\bar{\omega}$ is determined by Eq. 56. In fact, ν represents an average frequency of phonons contributing to the reaction coordinate Q of Eq. 41. Since the temperature dependence of the quantity on the right-hand side of Eq. 56 is weak, it can be estimated at high temperatures. Therefore, we get

$$\nu = \bar{\omega}/(2\pi) \approx (2\pi)^{-1} \left(\sum_j \omega_j^2 \lambda_j / \lambda \right)^{1/2} \quad (58)$$

with the reorganization energy λ in Eq. 39. Equation 58 was first derived by Rice [23]. The full semiclassical expression of $\bar{\omega}$ in Eq. 56 was given by the present author [24].

2.4 From the Adiabatic to the Non-Adiabatic Limit

2.4.1 Adiabaticity Parameter

Discrimination between the adiabatic and the non-adiabatic limit is deeply related to the uncertainty of quantum-mechanical observation of the product state by an electron at the reactant state (and vice versa) through the interaction J between them [24]. Let us consider that the reaction system is about to approach the crossing point $Q = Q_c$ in Figure 7 in the course of its time evolution $Q(t)$ on the reactant-state potential $V_r(Q)$ in the semiclassical regime. Let us denote by ε the energy difference between the reactant and the product state at the position $Q(t)$ of the reaction coordinate. Although atomic motions are treated semiclassically, an electron to be transferred always behaves quantum-mechanically. The quantum-mechanical energy modification brought about by the interaction J is given by J^2/ε in the second-order perturbation in J . The uncertainty principle of Heisenberg [6] predicts that the time required for this energy modification is at least of the order of $\hbar/(J^2/\varepsilon) (= \hbar\varepsilon/J^2)$. This means that it takes an amount of time of at least this order for the electron in the reactant state to fully recognize the product state through the interaction J between them. This time increases with an increase in the energy difference ε between the two states, or with a decrease in the interaction J . However, the reaction system moves along the reaction coordinate with an average velocity,

say, v , and it stays only for a time of $\sim 2\varepsilon/v$ in a region where the energy difference is smaller than ε . In this situation, we can consider the following two limits.

(a) $2J^2/(\hbar v) \gg 1$: In this limit, $\hbar\varepsilon/J^2 \ll 2\varepsilon/v$ is realized. Therefore, the passage of the reaction system through the crossing point $Q = Q_c$ in Figure 7 is so slow (or, the interaction J is so strong) that an electron in the reactant state has a sufficiently long time to observe the product state. Accordingly, the passage is accomplished with the reactant and the product states fully mixed quantum-mechanically. Therefore, transfer of the electron from the reactant to the product state has certainly taken place after a single passage. This situation can be described appropriately by the adiabatic potentials in Figures 1 and 6. We see, therefore, that the adiabatic limit is realized under inequality (a).

(b) $2J^2/(\hbar v) \ll 1$: In this limit, $\hbar\varepsilon/J^2 \gg 2\varepsilon/v$ is satisfied. Therefore, the passage of the reaction system through the crossing point $Q = Q_c$ is so fast (or, the interaction J is so weak) that an electron in the reactant state does not have a sufficient time to recognize the product state. Accordingly, the reactant and the product states are scarcely mixed quantum-mechanically in the course of the passage. Therefore, the transition of the electron from the reactant to the product state rarely takes place after a single passage. This situation can be described appropriately by the diabatic potentials in Figures 2 and 5. We see thus that the non-adiabatic limit is realized under inequality (b).

It is important that inequalities (a) and (b) do not depend on the magnitude of the energy difference ε between the reactant and the product state in the course of the passage. Therefore, they can be applied throughout the passage. (It is interesting to notice that such situations (a) and (b) arising from the uncertainty of observation can also be found in human relations, although we do not behave quantum-mechanically.)

Intermediate cases between (a) and (b) can be described by the Landau–Zener formula [25]. It was obtained in conjunction with a different problem of atomic collision of the second kind, where a collision of two atoms, say, A and B gives rise to ionized atoms, for example, A^+ and B^- . Since the energy of the product state ($A^+ + B^-$) decreases with a decrease in the interatomic distance because of Coulombic attraction, it crosses the energy of the reactant state ($A + B$) in this collision. A transition from the reactant to the product state takes place as a result of a transfer of an electron from A to B by the transfer interaction, say, J in the vicinity of the crossing point. This situation is schematically illustrated in Figure 8. When the speed with which the energy difference between the two state changes with variation of the interatomic distance is written as v , the formula tells us that the probability with which the ionized pair is found after the collision is given by

$$P(v) = 1 - \exp[-2\pi J^2/(\hbar v)] \quad (59)$$

Accordingly, $1 - P(v)$ gives the probability with which the ionized pair is not formed.

Here, $P(v)$ approaches unity when $2\pi J^2/(\hbar v) \gg 1$, describing situation (a) in the adiabatic limit. When $2\pi J^2/(\hbar v) \ll 1$, on the other hand, it approaches $2\pi J^2/(\hbar v)$,

Figure 8. Energies of the initial ($A + B$) and the final ($A^+ + B^-$) state in a collision of the second kind between atoms A and B, crossing one another with a change in interatomic distance.

which is much smaller than unity, thus corresponding to situation (b) mentioned above. In this non-adiabatic limit, $P(v) (\ll 1)$ can also be obtained by the perturbation calculation second-order in J , since it is proportional to J^2 . The perturbation calculation can be used only when $P(v) \ll 1$. In the opposite limit, $P(v)$ becomes saturated at a value of one, independent of J .

In the atomic collision, the v value has been determined extrinsically by the initial relative velocity of the two atoms. In the present problem of electron transfer between donor and acceptor, v takes various values, arising from the thermal fluctuations of atoms along the reaction coordinate. On a trajectory $Q(t)$ along the reaction coordinate in the semiclassical picture, the value of v is given by the time derivative $\dot{Q}(t)$ since Q was defined as the energy difference between the diabatic potentials for the reactant and the product state (Eq. 40). Since fluctuations in $\dot{Q}(t)$ are statistically independent of those in $Q(t)$, the average value of v is the same at any value of $Q(t)$.

The distribution function of $v [= \dot{Q}(t)]$ values has already been determined as $G(v)$ of Eq. 55. Since v itself, not v^2 , appears in the Landau-Zener formula (Eq. 59), and is regarded as a positive quantity, it is appropriate to estimate the average value of v by

$$\bar{v} \equiv \int |v| G(v) dv = 2\bar{\omega}(\lambda k_B T' / \pi)^{1/2} \quad (60)$$

where $\bar{\omega}$, determined by Eq. 56, represents the average angular frequency of phonons contributing to the reaction coordinate, λ represents the reorganization energy of Eq. 39, and T' represents the effective temperature of Eq. 44.

On the basis of the Landau-Zener formula (Eq. 59), the parameter for discriminating between the adiabatic and the non-adiabatic limits of ET should be given by

$$\gamma \equiv 2\pi J^2 / (\hbar \bar{v}) = \pi^{3/2} J^2 / [\hbar \bar{\omega} (\lambda k_B T')^{1/2}] \quad (61)$$

This dimensionless parameter has been called the adiabaticity parameter. When $\gamma \gg 1$, the adiabatic limit is realized, while the non-adiabatic limit is realized in the limit of $\gamma \ll 1$. As the average energy quantum $\hbar \bar{\omega}$ of phonons approaches zero, γ of Eq. 61 diverges, and only the adiabatic limit becomes justifiable. Born and Oppen-

heimer's idea of the adiabatic approximation [2] comes from this situation, as mentioned in Section 2.1.

In the non-adiabatic limit, the rate constant k can be calculated by Eq. 43 and is given by Eq. 35 with the effective temperature T' defined by Eq. 44, as mentioned before. Although k of Eq. 35 does not explicitly include the average angular frequency $\bar{\omega}$ of phonons, it is instructive to see that the preexponential factor of k is equal to $2\gamma(\bar{\omega}/2\pi)$: With the attempt frequency $\bar{\omega}/(2\pi)$ in Eq. 58, $(\bar{\omega}/2\pi)\exp(-\Delta G^*/k_B T')$ represents a rate per unit time with which the reaction system reaches the crossing point $Q = Q_c$ along the reaction coordinate Q as a result of thermal fluctuations of atoms in the reactant state. Each time the reaction system reaches the crossing point, it passes through the crossing point twice, that is, upward and downward, in a round trip from the bottom of the diabatic potential for the reactant state. Therefore, in the preexponential factor $2\gamma(\bar{\omega}/2\pi)$ of the rate constant, γ represents the average probability with which the transition of an electron from the reactant to the product state takes place per single passage in the non-adiabatic limit. This interpretation of γ is in accordance with its definition of Eq. 61 on the basis of the Landau-Zener formula (Eq. 59). We see, simultaneously, that the preexponential factor of the rate constant must be much smaller than the average frequency $\bar{\omega}/(2\pi)$ of phonons in the non-adiabatic limit for $\gamma \ll 1$.

2.4.2 Between the Adiabatic and the Non-Adiabatic Limit

The rate constant in cases intermediate to the adiabatic and the non-adiabatic limits can be obtained when the Landau-Zener formula (Eq. 59) is applied for each trajectory $Q(t)$ of the reaction system in the course of thermal fluctuations of atoms in the reactant state in the semiclassical regime [24]. We confine ourselves to a case where the barrier height ΔG^* for reaction is much larger than $k_B T$. In this case, $Q(t)$ can be regarded as starting from the bottom of the diabatic potential for the reactant state. Although the rate constant in the non-adiabatic limit is given by the same expression (Eq. 35) for the normal and the inverted cases (Figure 5), this situation cannot be obtained when we step beyond this limit.

Let us first investigate the inverted case in Figure 5, since it turns out that it is simpler than the normal case. In the inverted case, only two channels exist for a reactive trajectory $Q(t)$ along the reaction coordinate Q . As shown in part (a) of Figure 9, an electron makes a transition from the reactant state (state 1) to the product state (state 2) at time t_1 , when $Q(t)$ first passes the crossing point, in one channel. Just after the transition, both $Q(t)$ and its velocity $\dot{Q}(t)$ are conserved to those just before the transition in the semiclassical regime, as verified in Ref. [24], but $Q(t)$ begins to climb up the diabatic potential for state 2. Shortly after, $Q(t)$ returns to the crossing point at time t_{11} . As shown in part (b) of Figure 9, the electron does not make a return transition to state 1, and $Q(t)$ begins to descend down from the crossing point toward the bottom of the diabatic potential for state 2, the reaction in this channel being accomplished. In the other channel, shown in part (c) of Figure 9, the electron does not make a transition from state 1 to state 2 at time t_1 ; climbing up the diabatic potential for state 1, $Q(t)$ returns back to the crossing point

Figure 9. Two channels for a reactive trajectory $Q(t)$ of the reaction coordinate in the inverted case; one, (a) followed by (b), and the other, (c).

at time t_2 . Now the electron makes a transition from state 1 to state 2 without a change in its velocity, and the reaction in this channel is accomplished.

When the Landau-Zener probability, $1 - \exp[-2\pi J^2/(\hbar|v(t_i)|)]$ with $v(t_i) = \dot{Q}(t_i)$, is written as P_i , this trajectory $Q(t)$ has a reaction yield given by $P_1(1 - P_{11})$ in the first channel and $(1 - P_1)P_2$ in the second channel. How this result can be derived directly from the Hamiltonians in Eqs. 37 and 38 is shown in Ref. [24]. Since velocities $v(t_1)$, $v(t_{11})$, and $v(t_2)$ have approximately the same absolute value, they can be replaced by velocity $v(t_c)$ at the first crossing time $t_c = t_1$. Therefore, the reaction takes place with a yield given by

$$Y[\dot{Q}(t_c)] = 2P_c(1 - P_c), \quad \text{with } P_c = 1 - \exp\left(-\frac{2\pi J^2}{\hbar|\dot{Q}(t_c)|}\right) \quad (62)$$

in the inverted case in Figure 5, where a trajectory $Q(t)$ reaches the crossing point $Q = Q_c$ at time t_c from the bottom of the diabatic potential for the reactant state.

In the normal case, there is a series of channels for reactive trajectory $Q(t)$ where it starts from the bottom of the diabatic potential for the reactant state. In the first channel, described in part (a) of Figure 10, the electron makes a transition from the reactant state (state 1) to the product state (state 2) at time t_1 when $Q(t)$ first passes through the crossing point. After that, with the same velocity as before the transition, $Q(t)$ begins to descend down from the crossing point toward the bottom of the diabatic potential for state 2, and the reaction in this channel is accomplished. In the second channel, the electron does not make a transition to state 2 at time t_1 . $Q(t)$ continues to climb up the diabatic potential for state 1, and shortly after, at

Figure 10. First three channels for a reactive trajectory $Q(t)$ of the reaction coordinate in the normal case; the first one is shown in (a), the second one in (b) followed by (c), and the third one is shown in (d), followed by an event duplicating (c).

time t_2 , it returns back to the crossing point. As shown in part (b) of Figure 10, the electron makes a transition to state 2 without a change in its velocity, and $Q(t)$ begins to climb up the diabatic potential for state 2. Shortly after, it returns back to the crossing point at time t_{21} , as shown in part (c) of Figure 10. This motion of $Q(t)$ from t_1 to t_{21} has been called a swing [24]. After this swing, the electron does not make a return transition to state 1 at time t_{21} , and $Q(t)$ begins to descend down toward the bottom of the diabatic potential for state 2, the reaction in the second channel being accomplished. In the third channel, the electron makes a transition at time t_{21} again, and $Q(t)$ makes a swing once more, as shown in part (d) of Figure 10. After time t_3 in the course of the swing, $Q(t)$ returns back to the crossing point at time t_{31} (not shown in Figure 10), and the electron does not make a return transition to state 1, for accomplishment of the reaction in the third channel.

With the Landau-Zener probability P_i at time t_i , this trajectory $Q(t)$ has a reaction yield given by P_1 in the first channel, given by $(1 - P_1)P_2(1 - P_{21})$ in the second channel, given by $(1 - P_1)P_2P_{21}P_3(1 - P_{31})$ in the third channel, and so forth. The absolute value of the velocity $\dot{Q}(t)$ can be approximated to have the same magnitude at a series of the crossing times, as before. We have $P + (1 - P)^2P + (1 - P)^2P^3 + \dots = 2P/(1 + P)$ since $P^2 < 1$. Therefore,

$$Y[\dot{Q}(t_c)] = 2 \frac{P_c}{1 + P_c} \quad \text{with } P_c = 1 - \exp\left(-\frac{2\pi J^2}{\hbar |\dot{Q}(t_c)|}\right) \quad (63)$$

gives the yield in the normal case of Figure 5 at time t_c when a trajectory $Q(t)$ reaches the crossing point $Q = Q_c$ from the bottom of the diabatic potential for the reactant state.

The right-hand side of Eq. 52 gives the average frequency per unit time with which $Q(t)$ passes through the crossing point $Q = Q_c$ with a positive velocity $\dot{Q}(t)$ in the normal case or with a negative velocity in the inverted case. Therefore, for the rate constant k in a situation outside the adiabatic limit to be obtained, the thermal average over the trajectory $Q(t)$ on the right-hand side of Eq. 52 must be supplemented by the yield $Y[\dot{Q}(t_c)]$ obtained above, so that

$$k = \langle Y[\dot{Q}(t_c)] \delta(t - t_c) \rangle_r \quad (64)$$

Similar to the situation in Eq. 52, this expression for k appears to be time-dependent, but is not because of ergodicity satisfied after the averaging of $\langle \dots \rangle_r$ in thermal equilibrium. Just as Eq. 52 could be rewritten as Eq. 53, the rate constant k of Eq. 64 can be recast as

$$k = \frac{1}{2} \langle |\dot{Q}(t)| Y[\dot{Q}(t)] \rangle_r \langle \delta[Q(t) - Q_c] \rangle_r \quad (65)$$

Equation 54 gives $\langle \delta[Q(t) - Q_c] \rangle_r = (4\pi\lambda k_B T')^{-1/2} \exp(-\Delta G^*/k_B T')$ where ΔG^* is given by $Q_c^2/(4\lambda) = (\lambda + \Delta G)^2/(4\lambda)$ as the energy of the crossing point $Q = Q_c$ between the diabatic potentials. Therefore, k of Eq. 65 can be expressed as

$$k = \kappa (\bar{\omega}/2\pi) \exp(-\Delta G^*/k_B T') \quad (66)$$

when a factor κ is introduced. Here, κ supplements the average frequency per unit time, $(\bar{\omega}/2\pi) \exp(-\Delta G^*/k_B T')$, with which $Q(t)$ passes through the crossing point $Q = Q_c$ with a positive velocity $\dot{Q}(t)$ in the normal case or with a negative velocity in the inverted case. Therefore, κ represents the average probability with which reaction really takes place when the reaction system reaches the transition state as a result of thermal fluctuations in the reactant state. This κ (< 1) has been called the transmission coefficient in the transition-state theory [21]. From Eqs. 65 and 66, κ is given by $\langle |\dot{Q}(t)| Y[\dot{Q}(t)] \rangle_r (4\bar{\omega}^2 \lambda k_B T'/\pi)^{-1/2}$, where $\langle \dots \rangle_r$ is given by an average over the distribution function $G(v)$ [of Eq. 55] of the velocity $[v = \dot{Q}(t)]$ fluctuating in the reactant state. Thus, we obtain

$$\kappa = \frac{1}{4\bar{\omega}^2 \lambda k_B T'} \int |v| Y(v) \exp\left(-\frac{v^2}{4\bar{\omega}^2 \lambda k_B T'}\right) dv \quad (67)$$

In Eq. 67, $Y(v)$ is represented by Eqs. 62 or 63 in the inverted or normal case, respectively, with $v = \dot{Q}(t_c)$. We see, especially, that κ of Eq. 67 is a function only of the adiabaticity parameter γ of Eq. 61. When $\gamma \ll 1$, moreover, the two cases have the same κ , since both Eqs. 62 and 63 give $Y(v) \approx 4\pi J^2/(\hbar|v|)$. Therefore, we get, for both cases,

$$\kappa \approx 2\gamma \quad \text{for } \gamma \ll 1 \quad (68)$$

in the non-adiabatic limit. Shown in Figure 11 is the γ -dependence of κ , obtained

Figure 11. Transmission coefficient κ of the reaction as a function of the adiabaticity parameter γ in the normal and inverted cases.

by numerical calculation of Eq. 67 in Ref. [24]. When $\gamma \gtrsim 1$, κ deviates from the linear dependence on γ . In the adiabatic limit of $\gamma \gg 1$, κ approaches the saturation value of one in the normal case, since $Y(v) \approx 1$ in this limit in Eq. 67. In the inverted case, on the other hand, $Y(v)$ approaches zero in Eq. 67 and, hence, so does κ in this limit. The γ -dependence of κ in the both limits mentioned above is in agreement with that pointed out in Sections 2.3 and 2.4.1.

Estimating the integration in Eq. 67 by the method of steepest descent for $\gamma \gg 1$, we can obtain the asymptotic behavior in the γ -dependence of κ . In the normal case, inserting $Y(v) \approx 1 - \frac{1}{2} \exp[-2\pi J^2/(\hbar|v|)]$, obtained from Eq. 63, into Eq. 67, we obtain

$$\kappa \approx 1 - \frac{(\pi\gamma)^{1/3}}{2^{1/3}3^{1/2}} \exp\left(-\frac{3\gamma^{2/3}}{(4\pi)^{1/3}}\right) \quad \text{for } \gamma \gg 1 \quad (69)$$

In the inverted case, $Y(v) \approx 2 \exp[-2\pi J^2/(\hbar|v|)]$, obtained from Eq. 62, enables us to obtain

$$\kappa \approx \frac{2^{5/3}(\pi\gamma)^{1/3}}{3^{1/2}} \exp\left(-\frac{3\gamma^{2/3}}{(4\pi)^{1/3}}\right) \quad \text{for } \gamma \gg 1 \quad (70)$$

Therefore, in the adiabatic limit of the inverted case, the rate constant approaches

$$k \approx \frac{2\bar{\omega}}{3\sqrt{\pi}} \left(\frac{E_J}{k_B T'}\right)^{1/6} \exp\left[-\frac{\Delta G^*}{k_B T'} - \left(\frac{E_J}{k_B T'}\right)^{1/3}\right] \quad (71)$$

with

$$E_J \equiv 27\pi^2 J^4 / [4(\hbar\bar{\omega})^2 \lambda] \quad (72)$$

where $E_J \gg k_B T'$ under the condition of $\gamma \gg 1$. This asymptotic behavior with an additional thermal-activation factor was first pointed out by Christov [26].

2.5 Further Development

2.5.1 Large-Energy-Quantum Intramolecular Modes

When the donor–acceptor assembly is immersed in a solvent, the transferred electron interacts with both the atomic motions of the donor–acceptor super-molecule as well as the molecular motions in the solvent. In this situation, electron transfer gives rise to two types of reorganization, namely, atomic rearrangement within the solute molecules and molecular rearrangement in the solvent. The former has been called inner-sphere reorganization, and the latter outer-sphere reorganization [27]. The reorganization energy is written as λ_i for the former and λ_o for the latter. Energy quanta of molecular motions contributing to the latter are small, with magnitudes of at most ca. 100 cm^{-1} , while λ_o is usually larger than ca. 1000 cm^{-1} . Writing the average energy quantum of these molecular motions as $\hbar\bar{\omega}_o$, we see that the average Huang-Rhys factor $s_o = \lambda_o/(\hbar\bar{\omega}_o)$ is usually much larger than unity. Therefore, for outer-sphere reorganization the condition Eq. 33 for the semiclassical approximation is usually satisfied at all temperatures, where the effective temperature T' is given by Eq. 44 as an average over the various modes contributing to outer-sphere reorganization. This is the situation for which Marcus first constructed his theory on electron transfer in solution [7], taking into account only λ_o .

If intramolecular vibrations contributing to inner-sphere reorganization are also in the semiclassical regime, it is not necessary to separate the inner- and the outer-sphere reorganization as was done in the formulation in the previous sections. However, intramolecular vibrations with large energy quanta of ca. 1000 cm^{-1} and with appreciable reorganization energies of ca. 1000 cm^{-1} often contribute to inner-sphere reorganization. The average Huang-Rhys factor of these vibrations is not much larger than unity, and hence these vibrations cannot be treated within the semiclassical approximation.

In this situation, it is convenient to treat the large-energy-quantum modes by the single-mode approximation, where they are regarded as having a single energy quantum $\hbar\bar{\omega}_a$, contributing by an amount of λ_a to the inner-sphere-reorganization energy. In reality, $\hbar\bar{\omega}_a$ is determined as an average of various energy quanta of such modes. The remaining modes contributing to inner-sphere reorganization, as well as the outer-sphere-reorganization modes, are treated as in the semiclassical regime, and can be treated with the multimode model. We denote the contribution to the reorganization energy of these two kinds of modes in the semiclassical regime by λ , and the reaction coordinate given by a linear combination of their coordinates as in Eq. 41 by Q . Then, the diabatic potentials are given by the same $V_r(Q)$ and $V_p(Q)$ as in Eq. 42 for the reactant and product states, respectively. These semiclassical modes also determine the effective temperature T' (Eq. 44) as an average. Additionally, we take into account the large-energy-quantum modes at individual distortions described by coordinate Q . In this situation, the diabatic potential of the reactant state is composed of multiple parabolas of $V_r(Q) + m\hbar\bar{\omega}_a$ for $m = 0, 1, 2, \dots$, while that of the product state is composed of those $V_p(Q) + n\hbar\bar{\omega}_a$ for $n = 0, 1, 2, \dots$, as shown in Figure 12.

Figure 12. Diabatic potential for the reactant state composed of multiple parabolas of $V_r(Q) + m\hbar\omega_a$ for $m = 0, 1, 2, \dots$, and for the product state composed of $V_p(Q) + n\hbar\omega_a$ for $n = 0, 1, 2, \dots$, in a mutual arrangement of the normal case.

In the semiclassical regime, the value of coordinate Q must be conserved on transition of an electron from the reactant and the product state under the Franck–Condon principle. Since the diabatic potentials for these states are composed of multiple parabolas due to participation of large-energy-quantum intramolecular vibrations, the transition is specified by a simultaneous change in the quantum state of these vibrations, for example, from the m th state $|m; r\rangle$ in the reactant state to the n th state $|n; p\rangle$ in the product state for both m and $n = 0, 1, 2, \dots$. Therefore, in this case, the squared matrix element J^2 for the electronic part of the transition must be accompanied by $|\langle n; p|m; r\rangle|^2$, which is nonvanishing irrespective of $n \neq m$, since $|m; r\rangle$ and $|n; p\rangle$ are eigenstates of the intramolecular vibrations before and after their reorganization by energy λ_a .

At each crossing point between $V_r(Q) + m\hbar\omega_a$ and $V_p(Q) + n\hbar\omega_a$, we can define a reaction yield $\Upsilon_{n,m}(\dot{Q})$ per single forward passage with velocity \dot{Q} . It is obtained when J^2 is replaced with $|\langle n; p|m; r\rangle|^2 J^2$ in $\Upsilon(\dot{Q})$ of Eqs. 62 and 63 in the inverted and the normal case, respectively. Except in the non-adiabatic limit, $\Upsilon_{n,m}(\dot{Q})$ is in general not much smaller than unity, and the counter yield $1 - \Upsilon_{n,m}(\dot{Q})$ of no reaction after a single forward passage through the crossing point decreases from unity appreciably. In this situation, successive crossings in the course of time evolution of the reaction coordinate influence in each other's contribution to the rate constant. Such complexities do not occur in the non-adiabatic limit where J^2 is so small that $\Upsilon_{n,m}(\dot{Q})$ is much smaller than unity, and the rate constant is obtained simply as the sum of the yields at all possible crossing points. In this limit, $\Upsilon_{n,m}(\dot{Q}) \propto J^2$ has the same form for the normal and the inverted case. In the non-adiabatic limit, therefore, the rate constant is given by the thermal average over m and the sum over n on the right-hand side of Eq. 43 with $|\langle n; p|m; r\rangle|^2 J^2$ inserted for J^2 , as

$$k = \frac{2\pi}{\hbar} J^2 (1 - e^{-\beta\hbar\omega_a}) \sum_{m,n} |\langle n; p|m; r\rangle|^2 \langle \delta[Q - Q_c - (n - m)\hbar\omega_a] \rangle_r e^{-\beta m\hbar\omega_a}, \quad (73)$$

where we used $V_r(Q) + m\hbar\omega_a - [V_p(Q) + n\hbar\omega_a] = Q - Q_c - (n - m)\hbar\omega_a$ from Eq.

42, and $\langle \cdots \rangle_r$ represents the thermal average in q_j values on the right-hand side of Eq. 43.

Since Eq. 73 has the same structure as Eq. 22, it can be cast into a form similar to Eq. 23 with $n - m = \ell$. Since $\langle \delta(Q - Q_c - \ell \hbar \bar{\omega}_a) \rangle_r = F(Q_c + \ell \hbar \bar{\omega}_a)$ (from Eq. 54), Eq. 73 which gives the rate constant in the non-adiabatic limit can be expressed as

$$k = \frac{J^2}{\hbar} \left(\frac{\pi}{\lambda k_B T'} \right)^{1/2} \sum_{\ell=-\infty}^{\infty} F_{\ell} \exp \left(- \frac{(\lambda + \Delta G + \ell \hbar \bar{\omega}_a)^2}{4 \lambda k_B T'} \right) \quad (74)$$

with

$$F_{\ell} \equiv \exp \left[\frac{\beta \ell \hbar \bar{\omega}_a}{2} - s_a \coth \left(\frac{\beta \hbar \bar{\omega}_a}{2} \right) \right] I_{\ell} \left(\frac{s_a}{\sinh(\beta \hbar \bar{\omega}_a / 2)} \right) \quad (75)$$

where $s_a = \lambda_a / (\hbar \bar{\omega}_a)$ represents the Huang–Rhys factor for the large-energy-quantum intramolecular vibrations. This formula was first derived by Jortner [14].

In the limit of $s_a \rightarrow 0$, Eq. 74 reduces to Eq. 35, since $I_{\ell}(x) \rightarrow \delta_{\ell,0}$ for $x \rightarrow 0$. $\hbar \bar{\omega}_a$ ($\gtrsim 1000 \text{ cm}^{-1}$) is usually much larger than $k_B T$ ($\lesssim 200 \text{ cm}^{-1}$) below room temperature. Therefore, the interaction with the large-energy-quantum modes is usually in the atom-tunneling regime for any value of ℓ in Eq. 74, satisfying the condition (Eq. 28) where $\Delta G / (\hbar \bar{\omega})$, s , and $\bar{\omega}$ are replaced by ℓ , s_a , and $\bar{\omega}_a$, respectively. Hence, Eq. 74 reduces to

$$F_{\ell} \approx \begin{cases} e^{-s_a} s_a^{\ell} / \ell!, & \text{for } \ell \geq 0 \\ 0, & \text{otherwise} \end{cases} \quad (76)$$

since $\hbar \bar{\omega}_a \gg k_B T$ in the usual cases. When Eq. 76 is applicable, Eq. 74 means that transition of an electron from the reactant to the product state takes place at each crossing point between $V_r(Q)$ and $V_p(Q) + \ell \hbar \bar{\omega}_a$ for $\ell = 0, 1, 2, \dots$ in Figure 12, that is, at $Q = Q_c + \ell \hbar \bar{\omega}_a$ ($= \lambda + \Delta G + \ell \hbar \bar{\omega}_a$) from Eq. 42. In Figure 12, where diabatic potentials for the reactant and the product states are arranged in the normal case for $\lambda + \Delta G > 0$ of Figure 5, all the crossing points for $\ell \geq 1$ are located on the energy side which is higher along the reactant-state potential $V_r(Q)$ than that for $\ell = 0$. Therefore, Jortner's modification of Eq. 74 with Eqs. 75 or 76 is not very important in the normal region. His modification becomes crucial in the inverted region, that is, for $\lambda + \Delta G < 0$ of Figure 5, where the multiple parabolas above $V_r(Q)$ and those above $V_p(Q)$ are arranged as shown in Figure 13. In this case, the crossing point for $\ell = 0$ is located at $Q = Q_c$ ($= \lambda + \Delta G$) in the negative Q region along $V_r(Q)$, and in general, lower-energy crossing points with $|Q| < |\lambda + \Delta G|$ exist for certain values of $\ell \geq 1$, as seen also in Figure 13. Electron transfer takes place more rapidly through these lower-energy crossing points for $\ell \geq 1$ than through that for $\ell = 0$. In the inverted region, therefore, the rate constant becomes much larger than that given by Eq. 35, when large-energy-quantum intramolecular vibrations contribute to the inner-sphere reorganization with an appreciable reorganization energy $\lambda_a = s_a \hbar \bar{\omega}_a$.

Figure 13. Diabatic potentials for the reactant and the product state composed of the multiple parabolas as in Figure 12, but here shown for the inverted case.

Figure 14. $(-\Delta G)$ -dependence of the relative magnitude of the observed rate constant for electron transfer from biphenyl to various acceptor molecules where they are bridged by a spacer molecule at a distance ca. 17 Å in a glass at 77 K [18].

Such enhancement of the rate constant in the inverted region has, indeed, been observed by Miller and his collaborators [18]. They used biphenyl as a donor in a glass at 77 K. Various molecules were used as the acceptor for realizing various values of the free energy of reaction ΔG . Figure 14 shows the relative magnitudes of the observed rate constants of ET (scaled by the prefactor before the summation in Eq. 74) as a function of $-\Delta G$ which represents the free-energy drop of the reaction. When $-\Delta G \lesssim 0.8$ eV, the rate constant increases with an increase in $-\Delta G$, indicating that the reaction is in the normal region. When $-\Delta G \gtrsim 0.8$ eV, the rate constant decreases with an increase in $-\Delta G$, the reaction entering the inverted region. Since the average donor-acceptor distance is large (~ 17 Å), giving a small transfer integral J , the reaction is considered to be in the non-adiabatic limit. If the reaction is in the semiclassical regime as a whole, the rate constant k should be given by Eq. 35, and $\log k$ should change in proportion to ΔG^* equal to $(\lambda + \Delta G)^2/(4\lambda)$. When it is plotted as a function of $-\Delta G$, one obtains the so-called Marcus parabola peaking at $-\Delta G = \lambda$ and symmetric on the both sides. Figure 14 shows that the rate constant is much larger in the inverted region than expected from the Marcus parabola. This arises from participation of large-energy-quantum intramolecular vibrations in the

inner-sphere reorganization. The solid line in Figure 14 represents the theoretical fit to Eq. 74 with Eq. 75 for $\lambda = \lambda_a = 0.4$ eV and for $\hbar\bar{\omega}_a = 1500$ cm⁻¹ [18].

2.5.2 Electron Transfer to or from a Continuum of Free States

One of the central problems in semiconductor devices is the nonradiative capture of an electron of the conduction band into a localized defect level with energy deep in the forbidden gap [28]. Free electrons in the conduction band interact only weakly with phonons, but in such a localized state an electron interacts strongly with them [29]. This enables the localized state to capture a free electron with simultaneous emission of many phonons [30]. This type of electron transfer and the corresponding inverse process are slightly different from the electron transfer between localized states discussed before. In this case, either the donor or the acceptor is a collection of delocalized free states with a continuum of energy levels, while the other is a localized state with only a single energy level. Let us consider the case where the former is the donor and the latter is the acceptor. An example of diabatic potentials for describing these electron transfer processes is given by Figure 15, where $V_d(Q)$ represents that for the lowest free state above which a continuum of free states exists, as shown by thin solid lines, at each value Q of the reaction coordinate. The diabatic potential $V_p(Q)$ for the localized acceptor state in Figure 15 has a minimum shifted from that of $V_r(Q)$ due to strong interaction with the phonons. Capture and emission of free electrons by the deep level are also illustrated in Figure 15.

Let us denote by R_c the rate with which an unoccupied acceptor captures a free electron from the conduction band in a unit time, and by k_e the rate constant for emission of a captured electron from an occupied acceptor into the conduction band. Similarly to Eq. 15, the principle of microscopic equilibrium relating these is given by

$$(g_f n_T R_c / n) \exp(-\beta E_t) = g_i k_e \quad (77)$$

Figure 15. Diabatic potential $V_r(Q)$ for the lowest free state above which a continuum of free states exists, as shown by thin solid lines, at each Q value of the reaction coordinate. $V_p(Q)$ for the localized deep state has a minimum shifted from the minimum of $V_r(Q)$ due to a strong interaction with phonons.

where n , g_f , and g_t respectively represent the free-electron density, the number of equivalent valleys in the conduction band, and the degeneracy of the acceptor level whose energy is lower than the bottom of the conduction band by E_t (>0); n_T represents the effective density of conduction-band states available at temperature T in a single valley. For an effective mass m^* of free electrons in the conduction band, n_T is given by

$$n_T = [m^* k_B T / (2\pi\hbar^2)]^{3/2} \quad (78)$$

Since $R_c \propto n$, as an n -independent quantity, the capture cross-section σ_c is introduced by

$$R_c = n v_T \sigma_c \quad (79)$$

where $v_T \equiv (3k_B T / m^*)^{1/2}$ represents the average velocity of a free electron at temperature T .

Since each of the delocalized free states in the conduction band has only an infinitesimal amplitude at the site of the acceptor, electron transfer from each free state to the acceptor is always in the non-adiabatic limit. It was shown in Ref. [30] that the average magnitude \bar{J} of the transfer integral between them is of the order of B/\sqrt{N} , where B and N respectively represent the half-width of the conduction band and the total number of unit cells in the crystal. Therefore, a distinction between the normal and the inverted case similar to that given in Section 2.4 does not arise in the present problem [30]. To be more precise, both σ_c and k_e are saturated at a single value independent of B in the adiabatic limit for large B , irrespective of differences in the arrangement of the diabatic potentials similar to those shown in Figure 5.

The adiabaticity of ET in the present problem is determined by taking into account all the infinitesimal interactions between the individual conduction-band states and the localized acceptor state. For simplicity, we will hereafter confine ourselves to the classical regime for $k_B T \gg \hbar\bar{\omega}$, where $\bar{\omega}$, the average angular frequency of phonons contributing to the reaction coordinate Q , written as Eq. 41, is determined by Eq. 58. In this regime, the adiabaticity parameter is given by the following equation [30]:

$$\gamma = 4\sqrt{B}\lambda k_B T / [3\hbar\bar{\omega}(E_t + \lambda)^{3/2}] \quad (80)$$

where λ represents the reorganization energy of the reaction, as before. The parameter γ has a magnitude of the order of $Na^3 n_T \bar{J}^2 / [\hbar\bar{\omega}(\lambda k_B T)^{1/2}]$, with a^3 representing the unit-cell volume, since $(\hbar/a)^2 / m^*$ in $n_T a^3$ has a magnitude of the order of B . Therefore, γ has the same structure as the adiabaticity parameter γ of Eq. 61 for electron transfer between two localized states: The latter is of the order of $J^2 / [\hbar\bar{\omega}(\lambda k_B T)^{1/2}]$, while $Na^3 n_T$ in the former represents the total number of conduction-band states available in the whole crystal with volume Na^3 .

The adiabatic limit in this case corresponds to the situation where an electron is emitted from the localized acceptor state into the conduction band whenever large-amplitude fluctuations of atoms push the acceptor level up to the conduction-band

states. Therefore, k_e should approach the same form as Eq. 57 for ET between two localized states in the adiabatic limit. Accordingly, it is convenient to express k_e as

$$k_e = \kappa(\bar{\omega}/2\pi) \exp[-(\Delta G^* + E_t)/k_B T] \quad (81)$$

with the transmission coefficient κ as in Eq. 66, where $\Delta G^* = (\lambda - E_t)^2/(4\lambda)$ represents the thermal activation energy for the capture of free electrons by the acceptor. It was shown in Ref. [30] that κ is a function of only γ of Eq. 80, approaching

$$\kappa = \begin{cases} (3\pi/2)\gamma & \text{for } \gamma \ll 1 \\ 1 - (5\pi/9\sqrt{3})\gamma^{-2/3} & \text{for } \gamma \gg 1 \end{cases} \quad (82)$$

in the non-adiabatic and the adiabatic limit, respectively. The capture cross-section of the acceptor, σ_c , can be obtained from Eq. 81 for k_e , since they are related by Eqs. 77 and 79.

Usually, B is of the order of several eV, while both λ and E_t are at most several tenths of eV, and $\hbar\bar{\omega}$ is ca. 10 meV, determined by lattice vibrations. Therefore, the adiabaticity parameter γ of Eq. 80 is appreciably larger than unity, and hence the capture process is near the adiabatic limit of $\kappa \approx 1$. This feature was confirmed experimentally [30, 31].

2.5.3 Solvent-Fluctuation-Controlled Regime

A characteristic feature of the adiabatic limit is that the rate constant becomes independent of the transfer integral J or \bar{J} . This occurs because the electron to be transferred adjusts itself so rapidly to the motion of the atoms that the reaction is controlled only by the fluctuations of atoms which give rise to the transition state at $Q = Q_c$. It is important to note that this does not necessarily specify the same adiabatic limit mentioned so far. This behavior is, in fact, also possible in viscous solvents where molecular motions contributing to the outer-sphere reorganization are so slow that their speed controls the whole reaction. This situation is independent of whether the system is at the non-adiabatic or the adiabatic limit, while is characterized by the rate constant becoming only weakly dependent or completely independent of the magnitude of J or \bar{J} . This situation has been called the solvent-fluctuation-controlled (adiabatic) regime. There are, accordingly, two regimes for adiabaticity.

The traditional theory for the rate of chemical reactions is the transition-state theory [21] (abbreviated as TST). In fact, all the rate constants given so far in previous sections were formulated, in general terms, within the framework of the TST. It is tacitly assumed in this theory that fluctuations in the reactant state are so rapid that all the substates comprising the reactant state are always thermally equilibrated in the course of reaction. According to this assumption, the reactant population in the transition state is always maintained in thermal equilibrium with the population in the reactant state since both states are located on the reactant-state adiabatic (or diabatic) potential. Therefore, calculation of the rate constant is greatly simplified

in the TST, since we do not need to worry about how much of the population of the reactants is found in the transition state in the course of reaction. We only need to calculate the transmission coefficient κ in Eqs. 66 and 81, which gives the probability with which these reactants at the transition state proceed towards the product state. The assumption of thermal equilibration in the reactant state is reflected in the density matrix ρ_r of Eq. 21 used for calculation of the rate constant by Eq. 20, or in the Wigner distribution function of Eq. 47 for calculation of the thermally averaged $\langle \cdots \rangle_r$ in Eqs. 64 and 65.

When τ expresses the relaxation time of the molecular-arrangement fluctuations in a solvent, then, in the solvent-fluctuation-controlled regime, τ is so large (e.g., in viscous solvents) that reactions taking place in solute molecules are controlled by τ , with the rate constants decreasing with an increase in τ . In the TST, in contrast, the rate constant does, in principle, not depend on τ , since it has been assumed from the beginning that the substates of the reactant state corresponding to different arrangements of solvent molecules are always thermally equilibrated during reaction. This means that the solvent-fluctuation-controlled regime is located outside the framework of the TST.

Usually, τ is proportional to the viscosity of the solvent, η . In many kinds of solution reactions, the rate constant decreases with an increase in η [32]. These reactions cover not only elementary reactions such as electron-, excitation-, atom-group-transfer reactions, and isomerization reactions, but also composite reactions such as biological ones, including enzymatic reactions. The general formula for rates of solution reactions has not been clarified fully yet, in spite of solution reactions being one of the most central subjects in chemistry.

Outside the framework of the TST, we must determine the distribution of reactants among substates during the course of reaction. They differ in the arrangement of the solvent molecules around the reactive site. Already in 1940, when the TST was still in the process of being established [21], Kramers [33] treated such a regime theoretically. Molecular-arrangement fluctuations in solvents can be regarded as diffusive (i.e., Brownian) motions at least close to room temperature. Kramers modeled chemical reactions as surmounting a potential barrier from the reactant to the product well caused by diffusive motions of reactants along the one-dimensional reaction coordinate, as shown by the zigzag trajectory in Figure 16. In his reaction scheme, not only the surmount over the potential barrier but also the relaxation in the reactant well are simultaneously determined by the diffusive motions of reactants, without a priori assumption of their rapid thermalization in the reactant well. His theory, however, had not attracted much attention for a long time. It can be said that his theory was presented too early [34]. It is a natural order in the development of theories in science that an event (such as a reaction) causing a deviation from thermal equilibrium is first treated as a small perturbation on a thermalized system (as in the TST, but also more generally), as in the linear-response theory for kinetic coefficients [35]. His theory started to gain in popularity only in the 1980s, when dynamic effects in solution reactions, as non-TST behaviors, began to attract the attention of many people [36].

When we treat only diffusive motions in coordinate of reactants after rapid thermalization of their momentum, they can be described by the Smoluchowski equa-

Figure 16. A double-well potential for reaction $W(X)$ along a one-dimensional reaction coordinate X in the Kramers model, and a reactive diffusive trajectory represented by a zigzag line surmounting a reaction barrier from the reactant to the product well.

tion [37]:

$$\frac{\partial}{\partial t} P(X; t) = \frac{1}{\omega_o^2 \tau} \frac{\partial}{\partial X} \left[k_B T \frac{\partial}{\partial X} + \frac{dW(X)}{dX} \right] P(X; t) \quad (83)$$

where $P(X; t)$ represents the population of reactants at reaction coordinate X at time t in the double-well potential $W(X)$ in Figure 16. The curvature around the bottom of the reactant well in $W(X)$ is represented by ω_o^2 ; $W(X)$ can be expanded to

$$W(X) \approx \frac{1}{2} \omega_o^2 X^2 \quad \text{around } X = 0. \quad (84)$$

We can easily check that τ in Eq. 83 gives the relaxation time of diffusive motions of X in the reactant well: The temporal evolution of the average value of X is described by $\bar{X}(t) \equiv \int X P(X; t) dX$. Around the bottom of the reactant well, where Eq. 84 is applicable, Eq. 83 enables us to get the desired equation $d\bar{X}(t)/dt = -\bar{X}(t)/\tau$, by use of $\int X(\partial^2 P/\partial X^2) dX = 0$ and $\int X[\partial(XP)/\partial X] dX = -\bar{X}(t)$, obtained by partial integration.

Since the total number of reactants $\int P(X; t) dX$ is conserved in Eq. 83, its solution is, in equilibrium, described by the thermal equilibrium distribution $\exp[-\beta W(X)]$ in the double-well potential $W(X)$. The distribution relaxes toward this thermal-equilibrium one.

$W(X)$ in the vicinity of the top of its potential barrier, say, at $X = X_b$, is written as

$$W(X) \approx W(X_b) - \frac{1}{2} \omega_b^2 (X - X_b)^2, \quad \text{around } X = X_b \quad (85)$$

with a negative curvature $-\omega_b^2$. In the large- τ region of $\tau \omega_o^2/\omega_b \gg 1$, the forward rate constant given by the Kramers model of Eq. 83 approaches

$$k_{KR} \approx \frac{1}{\tau} \frac{\omega_b}{2\pi\omega_o} \exp\left(-\frac{W(X_b)}{k_B T}\right) \quad (86)$$

The characteristics of $k_{KR} \propto \tau^{-1}$ can easily be understood [38]: When $\tau = \infty$, friction retarding the motion of X becomes infinite in proportion to τ , and X cannot help stopping at a certain position. When τ is not infinite, although very large, X manages to move, but very slowly, as an accumulation of small movements back

and forth induced by collisions with solvent molecules with frequency proportional to τ . In this situation, it takes time proportional to τ for the X value to move over a definite length toward the product well. This is the reason why the reaction time given by Eq. 86 is proportional to τ .

Usually, τ is proportional to the viscosity, η , of solvents. Therefore, the Kramers model predicts that the rate constant becomes proportional to η^{-1} in viscous solvents. Indeed, in solution reactions, including electron transfer reactions, rate constants are known to decrease with an increase in η , as mentioned before. However, the observed dependence is not η^{-1} , but

$$k_{\text{obs}} \propto \eta^{-\alpha} \quad \text{with } 0 < \alpha \leq 1. \quad (87)$$

The reason for this discrepancy is that Kramers' model is inappropriate in describing ET reactions as the surmount over a potential barrier by diffusive motions of reactants, as shown in Figure 16. In ET reactions, the diffusive fluctuations occur as molecular rearrangement motions in a solvent, which give rise to outer-sphere reorganization. The reaction coordinate for ET reactions also contains intrasolute vibrational motions that give rise to inner-sphere reorganization. They are much faster than slow molecular-arrangement fluctuations in viscous solvents, with speeds characterized by vibration periods that are not influenced by the solvent viscosity. In this situation, ET reactions can be regarded as taking place at each arrangement of solvent molecules with the aid of intrasolute vibrational fluctuations. Such a model was proposed by Sumi and Marcus [39].

In this model, rearrangement motions of solvent molecules are described by a one-dimensional coordinate X , with energy described as $V(X)$. At each X value reaction takes place with an intrinsic rate constant $k(X)$ induced by the much faster intrasolute vibrational fluctuations. Then, the probability $P(X; t)$ with which the reaction system is found at X is regarded as being governed not by the diffusion equation of Eq. 83, but by a diffusion-reaction equation:

$$\frac{\partial}{\partial t} P(X; t) = \frac{1}{\omega_o^2 \tau} \frac{\partial}{\partial X} \left[k_B T \frac{\partial}{\partial X} + \frac{dV(X)}{dX} \right] P(X; t) - k(X) P(X; t) \quad (88)$$

Here, the potential $V(X)$ for diffusive fluctuations of X can be a single well potential with curvature ω_o^2 in the vicinity of its minimum of $X = 0$, because the reaction takes place due to the sink (i.e., the second term on the right-hand side). Let us describe the intrasolute vibrational motions, giving rise to the inner-sphere reorganization, by a coordinate q . This model is characterized by two components of reaction coordinate X and q . An example of the potential surface spanned by them is given in Figure 17, where the bottom O' of the product surface is distorted along the abscissa X by the outer-sphere reorganization energy λ_o , and along the ordinate q by the inner-sphere reorganization energy λ_i . The reactant and the product surfaces cross one another along line C, and electron tunneling takes place when the reaction system reaches this line in the course of thermal fluctuations along both coordinates on the reactant surface. Energy is lowest at point S on this line. Therefore, this point gives the location of the transition state. Three points O, S, and O'

Figure 17. Two-dimensional double-well potential for reaction in the Sumi–Marcus model spanned by slow (diffusive) molecular-arrangement fluctuations in solvents on the abscissa for the coordinate X and fast (ballistic) intrasolute vibrational fluctuations on the ordinate. Also shown is a reactive trajectory surmounting the transition-state barrier on the line C with an X -dependent rate constant $k(X)$.

are on a straight line, since both the reactant and the product surface are quadratic with the same curvature, by assumption (Figure 17). The reaction coordinate Q of Eq. 41 is nothing but a coordinate along this line. In the TST, trajectories on the reactant surface are not important since populations at each point are assumed to be always thermally equilibrated. Under this assumption, it is convenient to discuss the reaction along this reaction-coordinate line since the reaction can be related only to the fraction of the population that reaches the product surface through the transition-state point S .

In the Sumi–Marcus model of Figure 17, trajectories on the reactant surface are also important. Since molecular-arrangement fluctuations in solvents (the abscissa X) are assumed to be much slower than intrasolute-vibrational fluctuations (the ordinate q), a reactive trajectory should be the one shown in Figure 17: The reaction system is first taken to an X value by slow diffusive motions along the abscissa X , as represented by a zigzag line. Subsequently, when the reaction system is taken to line C by rapid vibrational motions on the ordinate q at this X value, electron tunneling takes place with an X -dependent intrinsic rate constant $k(X)$, as represented by a vertical straight line. For TST to be justified in this model, the most probable X value should be around that of the saddle point S .

At X on the abscissa in Figure 17, energy on the reactant surface is given by $\frac{1}{2}\omega_o^2 X^2$, while that on the product surface is given by $\frac{1}{2}\omega_o^2 (X - \sqrt{2\lambda_o}/\omega_o)^2 + \Delta G$. Therefore, the height of the line C from this X value on the abscissa is given by

$$\Delta G(X)^* = (\lambda + \Delta G - \omega_o \sqrt{2\lambda_o} X)^2 / (4\lambda_i) \quad (89)$$

where $\lambda \equiv \lambda_i + \lambda_o$ represents the total reorganization energy. This $\Delta G(X)^*$ gives the thermal activation energy of $k(X)$. Therefore, $k(X)$ can be expressed as

$$k(X) = \kappa \frac{\bar{\omega}}{2\pi} \exp[-\Delta G(X)^*/k_B T] \quad (90)$$

in the form of Eq. 66 in the classical regime, with the use of the transmission coefficient κ determined in Section 2.4.2, and the average angular frequency $\bar{\omega}$ of phonons contributing to the inner-sphere reorganization energy λ_i , determined by Eq. 58. When the reactant and the product surfaces are in the relative arrangement of the normal case, as in Figure 17, $k(X)$ of Eq. 90 is sufficient, as mentioned in Section 2.5.1. When they are in the relative arrangement of the inverted case, however, participation of large-energy-quantum intramolecular vibrations becomes important as pointed out in Section 2.5.1. An extension of the model, Eq. 90, along this line in the inverted case was pursued by Barbara and coworkers [40].

The rate constant derived from Eq. 88 was verified [41] to have the form

$$k = 1/(k_{\text{TST}}^{-1} + k_f^{-1}) \quad (91)$$

where k_{TST} represents the rate constant expected from the TST and is independent of the relaxation time τ of molecular-arrangement fluctuations in solvents, while the k_f term carries the τ dependence of k . Here, k_{TST} is given by the thermal average of $k(X)$ as

$$k_{\text{TST}} = \int k(X) e^{-\beta V(X)} dX / \int e^{-\beta V(X)} dX \quad (92)$$

Although an analytical expression of k_f has not been obtained yet, a systematic method for its calculation has been given [32, 41]. The k_f is proportional to τ^{-1} in its perturbational calculation of the lowest-order in $k(X)$, but it becomes proportional to $\tau^{-\alpha}$, with $0 < \alpha < 1$, when the perturbational calculation diverges [42]. To be more exact, k_f has a dependence as

$$k_f \propto \kappa^{1-\alpha} \tau^{-\alpha}, \quad \text{with } 0 < \alpha \leq 1 \quad (93)$$

where κ represents the strength of $k(X)$ in Eq. 90. When the thermal activation energy $\Delta G(X)^*$ of $k(X)$ is given by Eq. 89, it can be shown [32, 43] that α is given by

$$\alpha = \begin{cases} |1 - \lambda_i/\lambda_o|, & \text{for } 0 \leq \lambda_i/\lambda_o \leq 2 \\ 1, & \text{otherwise} \end{cases} \quad (94)$$

where the discontinuous derivatives of α at $\lambda_i/\lambda_o = 1$ and 2 should be rounded off, because the procedure for obtaining α becomes approximate at these points.

The component k_f decreases with an increase in the solvent viscosity, $\eta \propto \tau$. In low-viscosity solvents for $k_{\text{TST}} \ll k_f$, Eq. 91 reduces to $k \approx k_{\text{TST}}$, supporting TST. In high-viscosity solvents for $k_f \ll k_{\text{TST}}$, it reduces to $k \approx k_f \propto \tau^{-\alpha}$, invalidating TST. In this solvent-fluctuation-controlled regime, therefore, k becomes proportional to $\eta^{-\alpha}$, reproducing the observations of Eq. 87. When $\alpha < 1$, the control of the reaction by solvent fluctuations is only partial, since the rate constant still increases as $\kappa^{1-\alpha}$ with an increase in κ , which represents the strength of reaction in $k(X)$ of Eq. 90. The thermal-activation energy of the slow X motions is given by $\frac{1}{2}\omega_0^2 X^2$, which is appreciably smaller than that of k_{TST} given by the height of the transition state S in Figure 17. The reaction described by $k(X)$ contributes to k_f in proportion to $\kappa^{1-\alpha}$ in Eq. 93, but its thermal activation energy, $\Delta G(X)^*$, is also smaller than that of k_{TST} . Therefore, the thermal activation energy of k is smaller in the solvent-fluctuation-controlled regime ($k \approx k_f$) than in the TST regime ($k \approx k_{\text{TST}}$). This behavior can be detected if the solvent viscosity is kept constant to suppress a change in $\tau^{-1}(\propto \eta^{-1})$ which has a large activation energy in itself.

The η dependence of Eq. 87 has often been observed in isomerization reactions of organic molecules [32]. In such a case, it has been considered [43] that molecular-arrangement fluctuations in solvents give rise to cavities (i.e., free volumes) around a solute molecule, corresponding to slow diffusive motions along the abscissa in Figure 17. When the cavities are large enough, isomerization can take place by twisting motions which correspond to the rapid intrasolute vibrational motions along the ordinate in Figure 17.

The rate-constant formula of Eq. 91 is a general one, covering the whole range from TST to the non-TST regime in solution reactions. It can be applied not only to elementary reactions such as electron-, proton-, atom-group-transfer, and isomerization reactions in solvents, but also to biomolecular reactions such as enzymatic ones accomplished through a series of intermediate products. In fact, it has often been observed [32] that rate constants of biomolecular reactions decrease with an increase in the solvent viscosity, obeying Eq. 87. This means that such reactions are in the non-TST regime. In this case, slow diffusive fluctuations of solvent molecules drive those of the solvated conformation of a protein in which the reaction takes place. Observations of Eq. 87 indicate that biomolecular reactions are controlled by the slow speed of these fluctuations. This situation has often been referred to as *conformational gating* (or *control*). In the non-TST regime, the rate constants become smaller than k_{TST} .

Evolution over a long period has resulted in living organisms adapting beautifully their functions to their living conditions. It is interesting, then, to ask why they have “chosen” the non-TST regime with rate constants smaller than k_{TST} . It seems reasonable enough to answer [32] that they utilize solvent fluctuations (to be more exact, solvent-fluctuation-driven conformational fluctuations in the solvated structure of proteins) to accomplish their functions, positively utilizing the situation of *conformational gating*. Enzymes must execute at least three reaction steps (i.e., complex formation with a substrate, its transformation into the product, and its release). Each step requires a different conformation. To execute all of them by a single molecule, an enzyme must have a large flexible body, which can easily change its conformation diffusively in water each time a reaction step is accomplished.

Appendices

Appendix A: Direct Derivation of Equation 23

A term specified by m and n in the summation on the right-hand side of Eq. 22 describes an electron tunneling from donor to acceptor which is accompanied by the absorption of m phonons at the donor site and the emission of n phonons at the acceptor site. This process results from interaction between the electron and phonons with a coupling constant given by the Huang–Rhys factor s . The average number of thermal phonons, $\bar{n} = 1/(e^{\beta\hbar\bar{\omega}} - 1)$, is given by the Planck distribution for their energy quantum $\hbar\bar{\omega}$; the square of the electronic matrix element J is accompanied by $\exp(-s\bar{n})(s\bar{n})^m/m!$ for the absorption of m phonons and by $\exp[-s(\bar{n}+1)][s(\bar{n}+1)]^n/n!$ for the emission of n phonons [10]. The exponential terms arise from normalization which requires that the total sum of these factors in each category must be unity. Therefore, Eq. 22 should reduce to

$$k = \frac{2\pi}{\hbar} J^2 e^{-s(2\bar{n}+1)} \sum_{m,n} \frac{(s\bar{n})^m [s(\bar{n}+1)]^n}{m!n!} \delta[-\Delta G - (n-m)\hbar\bar{\omega}] \quad (\text{A1})$$

If $\Delta G \leq 0$ in Eq. (A1), $\ell \equiv n - m$ is positive, and we get F_ℓ in Eq. 23 by

$$\begin{aligned} F_\ell &= e^{-s(2\bar{n}+1)} \sum_{m=0}^{\infty} s^{(2m+\ell)} \bar{n}^m (\bar{n}+1)^{m+\ell} / [m!(m+\ell)!] \\ &= e^{-s(2\bar{n}+1)} \left(\frac{\bar{n}+1}{\bar{n}} \right)^{\ell/2} \sum_{m=0}^{\infty} \frac{(s\sqrt{\bar{n}(\bar{n}+1)})^{2m+\ell}}{m!(m+\ell)!}. \end{aligned} \quad (\text{A2})$$

This expression is equivalent to that of Eq. 24, since the summation in Eq. (A2) is equal to $I_\ell(2s\sqrt{\bar{n}(\bar{n}+1)})$ for $\ell \geq 0$, and $2\bar{n}+1$, $(\bar{n}+1)/\bar{n}$, and $\bar{n}(\bar{n}+1)$ can be expressed by $\coth(\beta\hbar\bar{\omega}/2)$, $\exp(\beta\hbar\bar{\omega})$, and $[2\sinh(\beta\hbar\bar{\omega}/2)]^{-2}$, respectively, in terms of Section 2.2.1.

Equation 24 for F_ℓ in Eq. 23 was derived above under the condition of $\Delta G \leq 0$. When $\Delta G > 0$, the backward rate constant, k_{BW} , can be obtained, since the reverse of the forward reaction for this free energy of reaction satisfies this condition. The value k_{FW} can be determined from k_{BW} by the relation of microscopic equilibrium, $k_{\text{FW}}/k_{\text{BW}} = \exp(-\beta|\Delta G|)$ in Eq. 15. The rate constant k given by Eq. 23 satisfies this relation without any modification, since $I_{-\ell}(x) = I_\ell(x)$. Therefore, Eq. 23 turns out to be applicable irrespective of the sign of ΔG .

Appendix B: Wigner Distribution Function

The rate-constant formula (Eq. 20) in the non-adiabatic limit is applicable irrespective of whether the phonon Hamiltonians H_r and H_p for the reactant and the

product state, respectively, consist of a single mode or of multimodes. Let us take the multimode model, where H_r and H_p are given by Eqs. 37 and 38, respectively.

Delta functions appearing on the right-hand side of Eq. 20 can be converted into exponential functions, as $\delta(E - H_p) = (2\pi\hbar)^{-1} \int \exp[-i(E - H_p)t/\hbar] dt$ and $\delta(E - H_r) = (2\pi\hbar)^{-1} \int \exp[i(E - H_r)t'/\hbar] dt'$. Substituting them into Eq. 20, we can integrate over E , to obtain $2\pi\hbar\delta(t - t')$. Consequently, we have converted the energy-integrated expression of Eq. 20 for the rate constant k into the time-integrated one

$$k = \frac{J^2}{\hbar^2 \text{Tr}[U_r(\beta)]} \int \text{Tr} \left[U_p \left(-i \frac{t}{\hbar} \right) U_r \left(\beta + i \frac{t}{\hbar} \right) \right] dt \quad (\text{A3})$$

with

$$U_b(x) = \exp(-xH_b) \quad \text{for } b = r \quad \text{or} \quad p \quad (\text{A4})$$

Here, x can be a complex variable under the condition that its real part is non-negative.

Quantum mechanics has various representations [6], for example, by eigenfunctions of observables in Schrödinger's picture, or by matrices in Heisenberg's picture. They can be treated equivalently in Dirac's picture by state vectors. The coordinate of a particle is an observable which can take continuous values. Eigenfunctions in Schrödinger's picture are the coordinate representation of state vectors in Dirac's picture. Equations 37 and 38 are the coordinate representation of phonon Hamiltonians H_r and H_p , where p_j is represented by $-i\partial/\partial q_j$ under the commutation relation $[q_j, p_{j'}] = i\delta_{j,j'}$. Both H_r and H_p are diagonal in this representation. Let us write eigenfunctions of H_r as $\Psi_M(\mathbf{q})$ with eigenenergy E_M for $M = 1, 2, 3, \dots$, where \mathbf{q} represents a multidimensional vector whose j th component q_j represents the coordinate of the j th phonon mode for $j = 1, 2, 3, \dots$. $\Psi_M(\mathbf{q})$ and E_M are composed of the $j(M)$ -th eigenfunction $\psi_{j(M)}(q_j)$ with eigenenergy $\varepsilon_{j(M)}$ of the j th mode, by

$$\Psi_M(\mathbf{q}) = \prod_j \psi_{j(M)}(q_j) \quad \text{and} \quad E_M = \sum_j \varepsilon_{j(M)} \quad (\text{A5})$$

The coordinate representation of $U_r(x)$ of Eq. A4 is expressed by $\Psi_M(\mathbf{q})$ and E_M as

$$\langle \mathbf{q}' | U_r(x) | \mathbf{q} \rangle = \sum_M \Psi_M(\mathbf{q}') \exp(-xE_M) \Psi_M(\mathbf{q})^* \quad (\text{A6})$$

The M summation on the right-hand side of Eq. A6 can be performed [44], giving

$$\langle \mathbf{q}' | U_r(x) | \mathbf{q} \rangle = \prod_j \frac{1}{\sqrt{2\pi \sinh(x\hbar\omega_j)}} \exp \left(-\frac{(q_j^2 + q_j'^2) \cosh(x\hbar\omega_j) - 2q_j q_j'}{2 \sinh(x\hbar\omega_j)} \right), \quad (\text{A6}')$$

with $\hbar\omega_j$ in Eq. 37. The validity of Eq. A6' can be checked by ascertaining that it satisfies $(\partial/\partial x + H_r)(\mathbf{q}'|U_r(x)|\mathbf{q}) = 0$ under the initial condition that $(\mathbf{q}'|U_r(x)|\mathbf{q})$ approaches $\prod_j \delta(q_j - q'_j)$ as $x \rightarrow +0$. The expression of $(\mathbf{q}'|U_p(x)|\mathbf{q})$ can be obtained if $q_j - \sqrt{2s_j}$ and $q'_j - \sqrt{2s_j}$ are substituted for q_j and q'_j on the right-hand side of Eq. A6' and the whole expression is simultaneously multiplied by $\exp(-x\Delta G)$. When $\int d\mathbf{q}$ represents the multidimensional integration with respect to q_j for $j = 1, 2, 3, \dots$, we can express $\text{Tr}[U_r(\beta)]$ and the t -integration part on the right-hand side of Eq. A3 by the \mathbf{q} integration, respectively, as

$$\text{Tr}[U_r(\beta)] = \int (\mathbf{q}|U_r(\beta)|\mathbf{q}) d\mathbf{q} = \prod_j \frac{1}{2 \sinh(\beta \hbar \omega_j / 2)} \quad (\text{A7})$$

and

$$\int dt \int d\mathbf{q} \int d\mathbf{q}' \left(\mathbf{q} \left| U_p \left(-i \frac{t}{\hbar} \right) \right| \mathbf{q}' \right) \left(\mathbf{q}' \left| U_r \left(\beta + i \frac{t}{\hbar} \right) \right| \mathbf{q} \right) \quad (\text{A8})$$

Substituting $(\mathbf{q}'|U_r(\beta + it/\hbar)|\mathbf{q})$ and $(\mathbf{q}|U_p(-it/\hbar)|\mathbf{q}')$ into Eq. A8, we can perform Gaussian integrations over \mathbf{q} and \mathbf{q}' , and see that Eq. A3 for the rate constant k can be cast into Eq. 31, where only the t integration remains to be executed for the calculation of k .

Wigner [22] introduced a new vector \mathbf{p} (composed of p_1, p_2, p_3, \dots) besides \mathbf{q} , so that

$$U_r(\mathbf{p}, \mathbf{q}) \equiv \int \left(\mathbf{q} + \frac{1}{2} \mathbf{b} \left| U_r(\beta) \right| \mathbf{q} - \frac{1}{2} \mathbf{b} \right) \exp(-i\mathbf{p} \cdot \mathbf{b}) d\mathbf{b} \quad (\text{A9})$$

This \mathbf{p} corresponds to the momentum conjugate to \mathbf{q} when \mathbf{q} corresponds to a coordinate vector of phonons. This can be checked by the mediation of an eigenfunction $\exp(i\mathbf{p} \cdot \mathbf{q})$ of the momentum operator $-i\partial/\partial \mathbf{q}$ for an eigenvalue \mathbf{p} . It has an amplitude projected onto the state of $\Psi_M(\mathbf{q})$, equal to $\Phi_M(\mathbf{p}) = \int \exp(-i\mathbf{p} \cdot \mathbf{q}) \Psi_M(\mathbf{q}) d\mathbf{q}$. The \mathbf{q} integration of $U_r(\mathbf{p}, \mathbf{q})$ of Eq. A9 can be shown to reduce to the thermal average of $|\Phi_M(\mathbf{p})|^2$, which gives the probability with which phonons of the state $\Psi_M(\mathbf{q})$ have a momentum \mathbf{p} :

$$\int U_r(\mathbf{p}, \mathbf{q}) d\mathbf{q} = \sum_M |\Phi_M(\mathbf{p})|^2 \exp(-\beta E_M) \quad (\text{A10})$$

The right-hand side represents the distribution function of the momentum vector \mathbf{p} . The \mathbf{p} integration of $U_r(\mathbf{p}, \mathbf{q})$ reduces to the thermal average of $|\Psi_M(\mathbf{q})|^2$, which gives the probability with which phonons of the state $\Psi_M(\mathbf{q})$ are found at coordinate \mathbf{q} ,

$$\int U_r(\mathbf{p}, \mathbf{q}) d\mathbf{p} \propto (\mathbf{q}|U_r(\beta)|\mathbf{q}) = \sum_M |\Psi_M(\mathbf{q})|^2 \exp(-\beta E_M) \quad (\text{A11})$$

The right-hand side represents the distribution function of the coordinate vector \mathbf{q} .

Equations A10 and A11 allow us to regard $U_r(\mathbf{p}, \mathbf{q})$ of Eq. A9 as the probability with which phonons can be found at coordinate vector \mathbf{q} with momentum vector \mathbf{p} (although it is not normalized yet). Since the coordinate and its conjugate momentum cannot be determined simultaneously at definite values in quantum mechanics [6], this probability must be approximate. In fact, it happens to have (nonphysical) negative values in some systems [22]. In phonon systems, fortunately, it is always positive, and it can be used as a semiclassical simultaneous distribution function for the coordinate \mathbf{q} and the momentum \mathbf{p} . After normalization, the Wigner distribution function thus obtained is given by

$$\rho_r(\mathbf{p}, \mathbf{q}) \equiv U_r(\mathbf{p}, \mathbf{q}) / \iint U_r(\mathbf{p}', \mathbf{q}') d\mathbf{q}' d\mathbf{p}' \quad (\text{A12})$$

Inserting Eq. A6' into Eq. A9 and performing Gaussian integrations over \mathbf{b} , we obtain an explicit expression of $U_r(\mathbf{p}, \mathbf{q})$, and of $\rho_r(\mathbf{p}, \mathbf{q})$ of Eq. A12. The $\rho_r(\mathbf{p}, \mathbf{q})$ thus obtained turns out to be given by Eq. 47, which is normalized as $\iint \rho_r(\mathbf{p}, \mathbf{q}) d\mathbf{q} d\mathbf{p} = 1$.

3 Single- and Multi-Electron Transfer Processes

Spiros S. Skourtis and David N. Beratan

3.1 Introduction

Many of the models for electron-transfer (ET) reactions discussed in this work assume the following: 1) just one electron is transferred, 2) the transfer occurs from donor to acceptor in a single step, and 3) the bridge is “rigid” during the process. Recent experimental and theoretical advances indicate that these assumptions are insufficient in many circumstances. Indeed, multi-electron, multistate, and dynamic bridge effects enrich the subject substantially. In this chapter we shall examine the influence of these effects on chemical and biological ET reactions.

We begin with a summary of the standard single-electron rigid-bridge model for electron transport [1, 2], and then describe effects that arise from bridge dynamics. We next examine issues in multistep multi-center electron transfer. The closely related problem of two-electron transfer is then discussed. Multi-center and multi-electron processes are of great relevance for ET in DNA, proteins, and catalytic reactions.

3.2 Single-Electron Transfer Reactions

The non-adiabatic ET rate is given by [1]

$$k_{\text{ET}} = \frac{2\pi}{\hbar} |T_{\text{DA}}|^2 (\text{FC}) \quad (1)$$

Here, T_{DA} is the tunneling matrix element between the donor (D) and acceptor (A) wave functions and (FC) is the Franck–Condon-weighted density of states. This is a description appropriate for an effective two-level system [3, 4, 5] with weak coupling

between donor- and acceptor-localized states. In the high-temperature regime, the continuum-solvent Gaussian model of Marcus predicts that the Franck–Condon factor is of the form

$$(\text{FC}) = \frac{1}{\sqrt{4\pi\lambda k_B T}} \exp[-(\Delta G^\circ + \lambda)^2 / 4\lambda k_B T] \quad (2)$$

where ΔG° is the standard free energy of the reaction, and λ is the solvent-reorganization energy (the sum of inner- and outer-sphere components), k_B is the Boltzmann factor, and T is the temperature. The tunneling matrix element, T_{DA} , reflects the electronic structure of the donor, acceptor, and bridging groups [6]. The two-level reduction of the ET problem results in the coupling [7, 8]

$$T_{\text{DA}} = \sum_{ij} (\mathbf{V} - E_{\text{tun}} \mathbf{S})_{\text{Di}} G_{ij}(E_{\text{tun}}) (\mathbf{V} - E_{\text{tun}} \mathbf{S})_{\text{jA}} \quad (3)$$

where \mathbf{V} is the electronic coupling matrix between the D(A) wavefunctions and bridge localized orbitals $i(j)$, \mathbf{S} is the overlap matrix, and E_{tun} is the tunneling energy of the electron. $G_{ij}(E_{\text{tun}})$ is the matrix element of the bridge Green's function between bridge orbitals i and j [8].

$$G_{ij}(E_{\text{tun}}) = [(E_{\text{tun}} \mathbf{S} - \mathbf{H})^{-1}]_{ij} \quad (4)$$

where \mathbf{H} is the Hamiltonian of the bridge. Here, the bridge is defined as the medium between D and A. T_{DA} grows as the energetics of the D and A species (E_{tun}) approach the bridge states. The rate formulation assumes that E_{tun} does not come close enough to the bridge state energies to destroy the validity of the two-level approximation [4, 5].

Numerical strategies for computing both the electronic and nuclear components of the ET rate are now rather advanced (see the chapter by Newton). For example, in both proteins and small molecules, finite-difference Poisson–Boltzmann methods are widely used for computing the outer-sphere component of the solvent reorganization energy λ_o [9, 10, 11, 12]:

$$\lambda_o = \left(\frac{1}{2}\right) \sum_i \Delta q_i^{\text{DA}} (\phi_i^{\epsilon_0} - \phi_i^{\epsilon_\infty}) \quad (5)$$

where \sum_i sums over points on a three-dimensional grid, Δq_i^{DA} is the change in electron density at grid point i when the electron is transferred, ϕ are the potentials at the grid points with the charge distribution given by Δq_i^{DA} , and the solvent dielectric is fixed at the static (ϵ_0) or optical values (ϵ_∞), respectively [1, 9]. These numerical calculations of λ_o reduce to the Marcus equation [1, 13] when a two-sphere description of the donor and acceptor is used. Methodologies for computing the electronic interaction rely upon direct applications of Eq. 3, or upon varying the

structure of donor and acceptor and searching for the “minimum energy splitting” (associated with $2T_{\text{DA}}$) between the initial- and the charge-transfer states. [8, 14].

In protein systems, where direct computation of T_{DA} proves challenging because of system size and structure, semi-empirical [15, 16, 17, 18, 19, 20], “divide-and-conquer” [21], and “pruned-protein” [22, 23, 24] approaches are frequently employed. The simplest empirical method is pathway analysis, which simply distinguishes the much more rapid decay of tunneling propagation through space compared to the decay through bond. For a given protein, empirical decay factors for tunneling propagation are assigned to all interatomic interactions on the basis of atom type and separation distances as established from X-ray crystallography. As such, the pathway strategy approximation is:

$$T_{\text{DA}} = A \times \text{Max} \left\{ \prod_i \varepsilon_i^{\text{C}} \prod_j \varepsilon_j^{\text{H}} \prod_k \varepsilon_k^{\text{S}} \right\} \quad (6)$$

where $\text{Max}\{\}$ represents the sequence of decay factors (between 0 and 1) associated with the strongest coupling pathway from D to A (i.e., resulting in the largest possible product of these factors). For a given protein structure, values of ε are assigned according to a simple recipe, depending on whether the contacts are covalent, hydrogen-bonded, or through-space [25]. The prefactor A depends on the donor and acceptor structure, and is approximately 0.1 eV for some proteins. T_{DA} is often compared for families of proteins with similar prefactors [26].

This simple view predicts that protein connectivity in a relatively compact region between donor and acceptor determines the strength of the coupling. Extensive analysis beyond the pathways level has supported the generic predictions of the model [21]: secondary structure influences the average decay of the coupling with distance; decay of rate with distance is not purely exponential but rather depends upon the tunneling medium; and hydrogen-bond connections [25, 27, 28] provide critical “short cuts” for tunneling propagation [29].

The pathway methodology has been used extensively to understand substantial rate differences that arise in the near activationless regime at equivalent distances [30, 31] (see chapter by Gray and Winkler). The connectivity of the medium in the zone between donor and acceptor can cause order-of-magnitude changes in rate. Moreover, secondary structure is found to cause differences in average decay exponents [31], as predicted by pathway analysis [25]. Creative pathway “engineering” was recently demonstrated by the building, binding, and characterizing of a cytochrome P-450 binding substrate tethered to an electron-transfer active species by a long methylene chain. Upon assembly, an approximately 20-Å covalent pathway was created between the surface ET active species and the heme.

Dutton and coworkers (see Dutton chapter) advocated analyzing T_{DA} in the context of the density of atoms in a zone between donor and acceptor. This is equivalent to the pathway analysis, because the density-dependent factor proposed by Dutton and coworkers [33] is:

$$T_{\text{DA}} \propto \exp\{-(R - 3.6)[f_{\text{atom}}\beta_{\text{atom}} + (1 - f_{\text{atom}})\beta_{\text{vac}}]\}. \quad (7)$$

Here f_{atom} is the fraction of the intervening medium filled by atoms and the two distinct β values characterize the through-bond and through-space propagation. This equation is easily rewritten in pathway language as [34]

$$T_{\text{DA}} \propto \varepsilon_{\text{c}}^{2N_{\text{c}}} \varepsilon_{\text{S}}^{2N_{\text{S}}} \quad (8)$$

where

$$\varepsilon_{\text{c}}^{2N_{\text{c}}} = \exp\{-f_{\text{atom}}\beta_{\text{atom}}(R - 3.6)\} \quad (9a)$$

and

$$\varepsilon_{\text{S}}^{2N_{\text{S}}} = \exp\{-(1 - f_{\text{atom}})\beta_{\text{vac}}(R - 3.6)\} \quad (9b)$$

As such, the pathway and density methods are the same, except for modest differences between the parameter sets employed. Both methods derive their protein-medium dependence from the decay (β) parameters for through-bond and through-space propagation. They both neglect to include explicitly multiple-pathway and quantum-interference effects, except through adopting parameters that might take these effects into account in an average sense. Analysis of T_{DA} in a multiple-pathway framework, including the effects of interfering paths, is now routine [21, 24, 35, 36]. For developing structure–function relationships from these more complex multi-orbital approaches, information-reduction schemes are needed. Examples of such schemes include importance-value [37] and electron-transfer contact-map analysis [38, 39]. A comprehensive review of structure–function analysis in electron transfer is given in Ref. [8].

Fluctuating bridge effects on electron transfer

Important to the structural interpretation of electron-tunneling mediation in proteins is an understanding of how a protein’s internal motion influences the tunneling from donor to acceptor. The structure–function analyses of tunneling described above are based on a “frozen” X-ray crystallographic (or energy-minimized) structure of the protein. A Hamiltonian is derived from a static protein structure—describing the atomic orbital energies and the interorbital interactions that give rise to through-bond and through-space couplings—and either a pathway or a higher-level analysis is carried out based on this Hamiltonian. However, in the case of long-distance electron transfer, the intervening protein bridge between donor and acceptor has enough time to undergo internal motions during the electron-tunneling reaction. The atomic-orbital energies and interorbital interactions thus change with time, limiting the validity of any frozen-structure description of tunneling.

Mikkelsen, Ulstrup, and Zakaraya [40], suggested a time-independent variational formulation for the treatment of the fluctuating-bridge problem. The starting point of their approach is the construction of free-energy functionals for the electron-transfer system when the electron occupies D or A. Each free-energy functional incorporates the electron’s kinetic energy, its potential energy of interaction with the

effective nuclear charges of the D and A atoms, and its interaction with the solvent inertial polarization. Each functional (F) is expressed in terms of the transition-state (nonequilibrium) inertial solvent polarization (\bar{P}_{in}^*), and the electron's wave function $\Psi_{\text{D}}(r)$ or $\Psi_{\text{A}}(r)$, that is, $F_{\text{D}} = F_{\text{D}}[\Psi_{\text{D}}, \bar{P}_{\text{in}}^*]$, $F_{\text{A}} = F_{\text{A}}[\Psi_{\text{A}}, \bar{P}_{\text{in}}^*]$. By relating \bar{P}_{in}^* in $F_{\text{D}}(F_{\text{A}})$ to the free energy of the reaction, ΔG° , the temperature, and the initial and final (equilibrium) inertial polarizations of the ET reaction, the authors obtained free-energy functionals that are functions of these variables and of $\Psi_{\text{D}}(r)$ and $\Psi_{\text{A}}(r)$. Minimization of these functionals with respect to $\Psi_{\text{D}}(r)$ and $\Psi_{\text{A}}(r)$ gives $\Psi_{\text{D}}(r)$ and $\Psi_{\text{A}}(r)$ "wave functions" whose tails depend on the above variables. Therefore, the corresponding matrix element between $\Psi_{\text{D}}(r)$ and $\Psi_{\text{A}}(r)$, T_{DA} , depends on the temperature and the free energy of the reaction. Although the approach is not explicitly time-dependent, it does allow for the interaction of the D and A "wave-function" tails with the solvent polarization at the transition state. The "wave functions" and T_{DA} obtained from this method are statistical (ensemble-averaged) quantities. The authors suggested that experiments on Ru-modified proteins that measure the free-energy dependence of the ET rate at different distances could illuminate the free-energy dependence of the rate that arises from T_{DA} "polarization." A more complete self-consistent approach based on this idea was later provided by Kuznetsov, Vigdorovich, and Ulstrup [41].

A different approach to this problem avoids the use of a statistical variational treatment. Rather, a two-state D–A Hamiltonian is assumed with an off-diagonal element T_{DA} that depends on some nuclear (bridge) coordinates and is thus time-dependent as these positions change. The two-state Hamiltonian is then used to compute a thermally averaged rate in the golden-rule non-adiabatic limit. An early example of this method is provided by Beratan, da Gama, Onuchic, and Hopfield [42, 43]. The authors assume that bridge vibrations y_i are coupled to T_{DA} through exponential decay factors of the form $\exp[-\beta(y_i - y_i^0)]$. This exponential dependence models the decay of T_{DA} across a through-bond or through-space contact (of length y_i) that oscillates harmonically around an equilibrium separation y_i^0 . The authors demonstrate that, in the golden-rule rate expression, this dependence introduces thermally averaged prefactors similar to the thermally averaged Franck–Condon factors arising from coupling of local modes to the electron's location at D or A. The averaging involves the probability of having different numbers of vibrational quanta in the bridge mode prior to electron transfer. As such, bridge fluctuations give rise to additional temperature-dependence of the rate that is solely due to the influence of bridge fluctuations on T_{DA} .

Alternative models for medium fluctuations explicitly incorporate the time-dependence of T_{DA} . Tang [44] analyzed the non-adiabatic rate behavior for a time-dependent T_{DA} with an exponentially decaying correlation function $\langle T_{\text{DA}}(t)T_{\text{DA}}(t + \tau) \rangle = T_{\text{DA}}^2 \exp(-\tau/\tau_c)$, and a vanishing average $\langle T_{\text{DA}} \rangle = 0$. For high temperatures and a long correlation time, τ_c , he was able to recover the static Marcus-rate expression. For intermediate τ_c , he found that T_{DA} fluctuations reduce the electron-transfer rate for small activation energies and increase the rate for systems with large activation energies. In the limit of very short τ_c , the rate becomes independent of the free-energy gap and reorganization energy, and is controlled solely by the T_{DA} fluctuations. These effects are most significant for systems with

large activation energies and are relevant to situations where there is, on average, zero or very weak coupling between donor and acceptor.

In an attempt to describe regimes with nonvanishing average T_{DA} values, Goychuk, Petrov, and May [45] adopted a different two-state model with $T_{\text{DA}}(t) = \langle T_{\text{DA}} \rangle + [(V_1 - V_2)/2]\alpha(t)$, where $\langle T_{\text{DA}} \rangle = (V_1 + V_2)/2 \neq 0$, $\alpha(t) = \pm 1$, $\langle \alpha(t) \rangle = 0$ and $\langle \alpha(t)\alpha(t+\tau) \rangle = \exp(-\tau/\tau_c)$. This model describes gated time dependence, where T_{DA} fluctuates stochastically between two different values (V_1 and V_2). The authors observed that the rate changes from adiabatic ($k \propto \tau_c^{-1}$) to non-adiabatic as τ_c decreases. For intermediate and short τ_c , the rate resembles a Marcus-like expression. For intermediate τ_c , the electronic coupling enters the rate as $\langle T_{\text{DA}}^2 \rangle$, whereas for short τ_c it appears as $\langle T_{\text{DA}} \rangle^2$. This analysis implies that interpretation of the ET rate should be based on such time-averages of T_{DA} .

Daizadeh, Medvedev, and Stuchebrukhov [46, 47] arrived at an expression for the non-adiabatic rate that does not assume a specific functional form for the time-dependence of T_{DA} . The overall ET rate for a reaction with free energy gap ΔG° and reorganization energy λ is expressed in their analysis as a weighted sum of Marcus-like rate functions (Eqs. 1 and 2). Each rate-expression element in the sum describes an inelastic tunneling process during which the electron exchanges energy ε_n with bridge vibrations. The weight of the process is the probability of energy exchange $P(\varepsilon_n)$, and the sum is over all possible ε_n (as in [43]). In each rate-expression element, T_{DA}^2 is replaced by $\langle T_{\text{DA}}^2 \rangle$ and the standard free energy of the reaction ΔG° is replaced by an “effective” free energy $\Delta G^\circ + \varepsilon_n$. The contribution of no energy exchange ($\varepsilon_n = 0$) corresponds to elastic tunneling and is described by the standard nonadiabatic rate expression (ΔG°). If the electron absorbs energy from the bridge vibrations as it tunnels ($\varepsilon_n < 0$), it feels a reduced “effective” free energy in comparison to the case of no energy exchange (i.e., $\Delta G^\circ + \varepsilon_n < \Delta G^\circ$). If it loses energy ($\varepsilon_n > 0$), it feels an increased “effective” free energy ($\Delta G^\circ + \varepsilon_n > \Delta G^\circ$). The authors offer an expression for the probability of energy exchange $P(\varepsilon_n)$ in terms of the bridge eigenstates and their Boltzmann populations. This probability is generally D–A distance dependent (the longer the bridge the higher the probability of energy exchange), giving rise to regimes where the rate is enhanced as the D–A distance increases, in analogy to the earlier non-Born–Oppenheimer results of Beratan and Hopfield [48].

The functional form of the ET rate formulated in Refs. [46, 47] suggests that its free-energy dependence can be very different from the free-energy dependence of the classical (elastic) Marcus rate expression. The rate is a sum of Gaussians of identical widths, centered at different free-energy values ($-\lambda - \varepsilon_n$). Therefore, the rate as a function of free energy is described by an envelope of Gaussian functions with a much larger composite width than each individual component. Since the weight of each Gaussian, $P(\varepsilon_n)$, is both D–A-distance and temperature-dependent, the envelope is also distance- and temperature-dependent. These observations led the authors to suggest that experiments measuring distance and temperature effects on the free-energy dependence of ET rates will shed light on the inelastic tunneling contributions to the rate. In particular, they find that their rate expression is consistent with the free-energy-dependent measurements of Winkler, Gray, and

coworkers on Ru-modified myoglobins [49], that indicated the lack of an inverted region. It is not possible to experimentally deconvolute the inelastic-tunneling contributions to the free-energy dependence from other effects, as similar effects could arise from local modes coupled to donor and acceptor or from electron transfer to an excited state of the acceptor [49].

Wolfgang, Risser, Priyadarshy, and Beratan [50] analyzed the dependence of T_{DA} on the geometry of peptides. They computed the bridge Green function that enters T_{DA} for different geometries of fluctuating α -helical and β -strand polypeptides by using CNDO/S methods at different fixed tunneling energies. They observed that the Green function (and hence T_{DA}) changes sign and magnitude with structural variation. Similar observations were later made by Daizadeh et al. [46] in extended-Hückel calculations of T_{DA} for different geometries of a segment of azurin at two tunneling energies. Both studies demonstrate large fluctuations in T_{DA} on short timescales (tens of fs). In a similar study, Kurnikov, Zusman, Kurnikova, Farid, and Beratan showed that geometrical fluctuations cause significant changes in both T_{DA} and λ for covalently linked iridium-pyridinium D–A systems [9]. An understanding of these geometry-dependent parameters is essential for understanding the observed electron-transfer rates.

The validity of the two-state description for a fluctuating D–bridge–A system was examined by Xie, Archontis, and Skourtis [51]. Rather than assuming a two-state Hamiltonian from the start and using it in an expression for the rate, they solved the time-dependent Schrödinger equation for a fluctuating β -sheet bridge using a time-dependent Hamiltonian for the entire system (obtained from CNDO calculations performed every fs of classical molecular dynamics). With the electron initially in a D state, they computed the probability of electron transfer to an A state as a function of time. They then constructed time-dependent two-state Hamiltonians that, when introduced to the time-dependent Schrödinger equation, reproduced the main features of the electron-transfer probability accurately. Their analysis shows that such effective D–A Hamiltonians must necessarily contain $T_{\text{DA}}(t)$ with a time-dependent tunneling energy. Fixed tunnelling-energy effective Hamiltonians (and hence fixed-tunneling energy $T_{\text{DA}}(t)$ values) may lose their validity on short timescales. This effect should be taken into account when studying T_{DA} as a function of structural fluctuations (Figure 1). In Ref. [51], the ET probability for the fluctuating β -sheet bridge and the static bridge were compared by using identical sets of D–A pairs. The timescale of deviation of the two probabilities was studied as a function of increasing D–A distance.

Ungar, Newton, and Voth [52] have simulated an electron-transfer system consisting of a solvated proline tetramer with transition-metal D and A. Their starting point was the non-adiabatic (golden-rule) expression for the rate, with a time-dependent T_{DA} (as in [44, 45, 46, 47]). A detailed study of the free-energy dependence of the rate was performed with the use of molecular-dynamics simulations, for which enthalpic and entropic effects were separated. The time-dependence of T_{DA} was also analyzed at the INDO/S level, and significant T_{DA} fluctuations were observed at fixed D–A distances, as in Refs. [46, 47, 49, 50]. The computational methods employed in [52] are promising for simulating conformationally fluctuat-

Figure 1. ET dynamics characteristics of a fluctuating β -sheet. (a) dyn. br. The electron-transfer probability between the α -carbons of Met 121 and Gly 123 (D–A pair) of the β -sheet of azurin. The “dynamic bridge” probability is computed by solving the time-dependent Schrödinger equation with a time-dependent Hamiltonian for the entire β -sheet system. The Hamiltonian is constructed at the CNDO level from classical molecular dynamics trajectories of the solvated azurin molecule. (b) dy2s with constant E_{tun} . The ET probability is computed using the time-dependent Schrödinger equation with an effective time-dependent two-state (D–A) Hamiltonian obtained from the full Hamiltonian in (a) via projection (the “dynamic two-state approximation” [51]). E_{tun} is kept constant at -9 eV. The probability deviates from its exact counterpart in (a) (dyn. br.) within 400 fs. (c) dy2s with variable E_{tun} . The ET probability computed using a “dynamic two-state approximation” with time-dependent E_{tun} . For a good approximation of the exact electron-transfer probability (dyn. br.) for $t > 400$ fs, the tunneling energy (E_{tun}) used in the projection of the “dynamic two-state” approximation must be varied as a function of time. The time dependence of E_{tun} in (c) is shown at the top of the figure, where it is compared to the E_{tun} value of -9 eV used in (b).

ing ET systems. As pointed out by the authors, a central goal in this area is to compute the probability of accessing conformations with large T_{DA} values, and hence to understand their contributions to the rate.

Fluctuations in geometry may cause ET mechanism changes as well as introduce T_{DA} modulation and inelastic tunneling. Long-range ET processes may proceed in a single coherent step from donor to acceptor, or may be incoherent (involving many short-range hops) with localization and trapping at intervening sites. What

determines the propensity for one mechanism or another is the Boltzmann penalty factor for populating sites that may be “uphill” ($\exp[-\Delta E/k_B T]$) compared to the tunneling penalty factor ($\exp[-\beta R_{DA}]$). For transport distances of 40 Å with β values of 1 Å⁻¹, the two exponents are about equal at room temperature. As such, the mechanisms should compete with one another at very long distances. In instances of competition, the relaxation dynamics of the intermediate states is critical for determining the ET dynamics.

In a pure two-level system in which an electron is launched from the donor at time, $t = 0$, its probability of being found on A rises as $\sin^2[(T_{DA}/\hbar)t]$ and leads to ET rates proportional to $|T_{DA}|^2$. Even at zero temperature, the two-level approach for describing the ET rate processes may fail. This may be the case because interatomic interactions lead to substantial electronic population of the bridge-centered orbitals. That is, when mixing between donor and bridge states becomes comparable to the energy gap between donor/acceptor and bridge states, the electronic dynamics is no longer well described by the two-level description. As bridge states approach D and A in energy, the simple $\sin^2[(T_{DA}/\hbar)t]$ envelope is destroyed, and substantial amplitude arises on sites other than donor and acceptor. An illustration of such behavior appears in Ref. [53], where a two-state approximation could not be readily used for the prediction of a rate.

Three-state electron transfer

A critical issue in ET concerns the crossover from pure superexchange mediation via bridge orbitals to a mechanism involving substantial population of the bridging orbitals. Considerable electronic amplitude can move through the bridge coherently, or—alternatively—relaxation processes may further trap amplitude on the bridge. Recent studies have formulated the problem in such a way that one may interpolate between these two limiting regimes [1, 2].

The three-state (three-potential-energy surface) problem is of interest for redox chains, chemical triad model systems, DNA electron transfer, and the primary charge separation in photosynthesis. As there are two energy-gap fluctuations in these reactions, and the fluctuations are not simply related to each other (in contrast to the case of two-electron transfer in two-center systems, *vide infra*), the problem is intrinsically two-dimensional. Marchi et al. [54], Zusman and Beratan [55], and Okada and Bandyopadhyay [56] have analyzed the nature of these potential energy surfaces and the electron-transfer kinetics. In the steady-state approximation for species 2,

$$k_{13} = \frac{k_{12}k_{23}}{k_{21} + k_{23}} + k_{13}^S \quad (10)$$

the rates k_{12} , k_{21} , and k_{23} describe electron transfer between neighboring sites, while k_{13}^S describes superexchange-mediated transfer from site 1 to 3. A new geometry-dependent parameter b arises to describe these reaction rates. This parameter, associated with the size and position of the three ET species, can be estimated from

simulation [54] and in a three-sphere model [55]

$$b = \frac{(1/R_1) - (1/|\mathbf{r}_2 - \mathbf{r}_1|) - (1/|\mathbf{r}_3 - \mathbf{r}_1|) + (1/|\mathbf{r}_3 - \mathbf{r}_2|)}{(1/R_1) + (1/R_3) - (2/|\mathbf{r}_3 - \mathbf{r}_1|)} \quad (11)$$

where R_1 is the radius of the donor, R_3 is the radius of the acceptor, \mathbf{r}_1 is the vector position of the donor, \mathbf{r}_2 the vector position of the bridge, and \mathbf{r}_3 the vector position of the acceptor. An approximate perturbation-theory estimate for the superexchange coupling averaged over fluctuation of the intermediate state coordinates is the following equation [55]

$$\bar{T}_{DA} \approx \frac{V_{12}V_{23}}{\Delta G_{12} + \lambda_{12} - b(\Delta G_{13} + \lambda_{13})} \quad (12)$$

which generalizes the two-sphere model expression [13]. The interplay between the superexchange matrix element and the free-energy dependence of the stepwise vs. superexchange rate channels leads to nonparabolic dependencies of k_{13} on the overall reaction free energy. Several groups [57, 58] have employed rate analysis along these lines in an attempt to ascertain the reaction mechanism for the primary charge separation event(s) in photosynthesis, which involve the special pair (electron donor), a bridging chlorophyll (supporting a real or virtual intermediate state), and a pheophytin (electron acceptor) species (see Figure 2a). This mechanistic issue in the reaction center remains somewhat open, and is complicated by questions of whether the initial or the intermediate species (if it exists) equilibrates thermally during the transport process [59].

Multistate electron transfer

DNA is an electron-transfer bridge that can access multistep hopping under some circumstances. Although of interest for some time [60], DNA ET has received focused interest recently through a series of innovative studies with well-defined donor and acceptor groups (see chapter by F.D. Lewis). In Barton's group, studies with intercalated donor and acceptor transition-metal species and with tethered and intercalated species suggested soft distance dependence for excited-state quenching in DNA [61, 62, 63, 64]. A body of recent experiments, utilizing DNA base oxidation, indicate a range of distance dependencies and a role for both short-distance superexchange-mediated transport as well as long-distance multistep hopping transport [65, 66, 67, 68, 69, 70]. Although the long-range superexchange coupling between distant bases is predicted by theoretical studies to decay rapidly with distance [71, 72], much softer apparent distance decays may be observed if multistep short-range hopping is energetically accessible [1]. In the multistep scenario, superexchange plays a role, mediating each hop between bases at relatively small distances. There is evidence, as well, for single-step long-range superexchange transfer in DNA with substantial distance decay [65, 66, 68]. Ongoing theoretical and experimental studies of sequence, geometry, and donor/acceptor dependence are revealing a great richness and diversity of mechanisms [70].

Figure 2. (a) The ET pathways in the bacterial photosynthetic reaction are shown proceeding from the special pair (B) via the bridging bacteriochlorophyll (BC) to the bacteriopheophytin (BP) (the right-hand branch is active). Arrows represent the nearest-neighbor interactions between chromophores. The B-BC and BC-BP interactions may produce either a real or a virtual intermediate localized on BC during the reaction [88]. (b) A proposed vibronically-coupled hole-hopping mechanism for ET in DNA is shown [69]. This mechanism emphasizes the delocalization of the hole.

3.3 Multi-Electron Transfer Reactions

Multi-electron transport is particularly important in catalytic biological systems. For example, biological nitrogen fixation involves the delivery of eight electrons to nitrogenase [73]. A great challenge is to understand the choreography of electron delivery and of coupled electron proton transfer in catalytic systems. In many biochemical instances, the ET reactions occur one by one and are well described by the ET theories discussed above. Many redox couples ($\text{Pt}^{2+}/\text{Pt}^{4+}$ for example) also involve stable species whose charge differs by two. We now consider the issue of single vs two-electron transport (outer sphere, without coupled proton transfer). This serves as an example of another three-state and “three-parabola” problem. We are particularly interested in the rates of competing single-step and concerted two-(or multi)-electron events. Closely related mechanistic issues arise when the competing superexchange and hopping pathways discussed earlier are considered.

In a unimolecular ET system (or a fixed contact ion pair), the kinetic equations

lead, in the steady-state approximation for D^-A^- , to the overall rate for the two-electron transfer being given by the following equation [74, 75, 76]:

$$k_{13} = \frac{k_{12}k_{23}}{k_{21} + k_{23}} + k_{13}^C \quad (14)$$

where k_{13}^C is the rate of concerted two-electron transfer from donor to acceptor. Formulation of the three-parabola framework for the two-electron problem is relatively straightforward. Assuming a simple charge distribution on the two centers (such as two charged spheres) and that the shape of the charge distributions does not change upon ET (allowing only the amount of charge on D and A to vary), the energy gap fluctuations associated with single electron ET and those associated with concerted two-electron ET are proportional to one another [74]. Moreover, the reorganization energies differ by a factor of four, since the reorganization energy scales with the amount of charge transferred squared. As such, two-electron transfer is described by three parabolas along a (one-dimensional) reaction coordinate, with the minima of the free-energy parabolas spaced equally along the reaction coordinate in the order $D^{\bullet}=A$, $D^{\bullet}A^{\bullet-}$, DA^{\bullet} . The steady-state approximation is that the single-electron transfer species is of fixed concentration, valid in the regime where the ET reaction proceeds via an unstable $D^{\bullet}A^{\bullet-}$ intermediate. The electronic coupling interaction for two-particle tunneling is anticipated to be smaller (the virtual intermediate energy will be approximately twice as large) than in the case of single-electron tunneling.

The mechanistic regimes involving unstable D^-A^- intermediates are summarized in Figure 3. In (a), the activation barrier for stepwise transfer (crossing points of

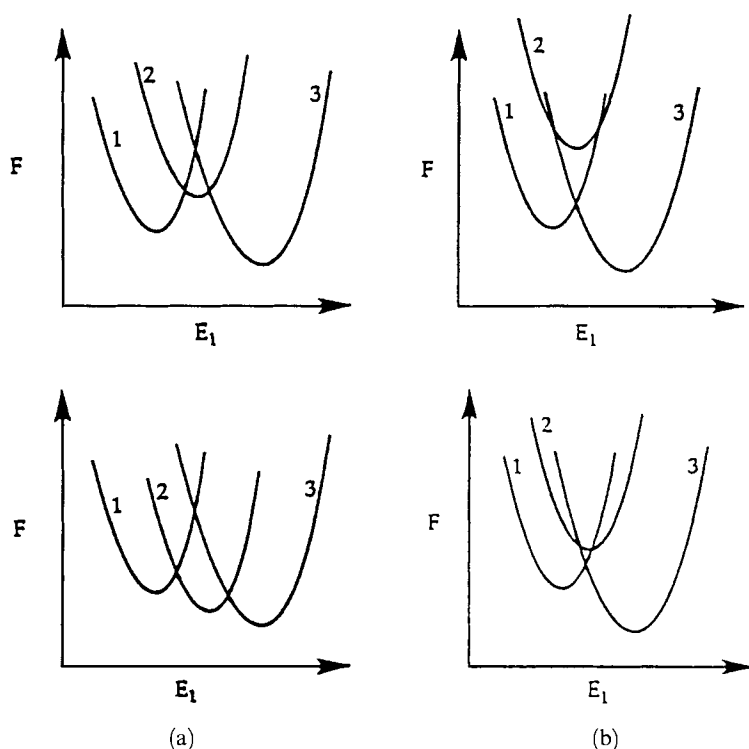

Figure 3. The potential energy surfaces for two-electron transfer involves the states $D^{\bullet}A$ (1), $D^{\bullet-}A^{\bullet-}$ (2), and DA^{\bullet} (3) [75]. Assuming that only the amount of charge on D and A changes upon ET (but that the shape of its distribution does not change), the problem maps onto a one-dimensional reaction coordinate with equally spaced wells. The competition between sequential and concerted (two-electron) mechanisms is determined by the positions of the crossing points between wells and the magnitude of the one- and two-electron coupling matrix elements. In (a), the activation energy associated with the stepwise mechanism is lower than that for the concerted process. In (b), the reverse ordering of activation energies is shown.

curves 1 and 2, and 2 and 3) is lower than the barrier for concerted transfer (crossing point of curves 1 and 3). In (b), the activation energy for the concerted channel dominates.

The activation free energies for the stepwise (two-step) transport process may fall into two regimes. For an unstable intermediate species (species 2, $D^{\bullet-}A^{\bullet-}$) with free-energy minimum below the crossing point of curves 1 ($D^{\bullet}A$) and 3 (DA^{\bullet}) [75]

$$\Delta F^{\ddagger} = \frac{[\Delta G_{21} + (\lambda_{31}/4)]^2}{\lambda_{31}} \quad (15a)$$

λ_{13} is the reorganization energy associated with concerted two-electron transfer from $D^{\bullet}A$ to DA^{\bullet} ; the reorganization energy for the single-electron steps is $\frac{1}{4}$ of

Figure 4. Plots of (log) rate vs ΔG_{13} for fixed ΔG_{12} in a two-electron transfer system. Note the weak dependence on driving force for small driving forces and the parabolic Marcus-like regime at higher driving forces [75].

λ_{13} . For an unstable intermediate with free-energy minimum above the crossing point of curves 1 and 3

$$\Delta F^\ddagger = \frac{[\Delta G_{32} + (\lambda_{31}/4)]^2}{\lambda_{31}} \quad (15b)$$

Finally, for the concerted two-electron transport (the curve 1–curve 3 crossing process)

$$\Delta F^\ddagger = \frac{(\Delta G_{31} + \lambda_{31})}{4\lambda_{31}} \quad (15c)$$

Figure 4 shows the rate dependence on overall free energy (ΔG_{13}), with ΔG_{12} held fixed for two-electron ET. In the pure concerted regime (right-hand side of diagram), the Marcus parabolic dependence with a reorganization energy four times that of the one-electron value is obtained. In the stepwise regime, the activation energy is controlled by the fixed value of ΔG_{12} , and the reaction rate is weakly dependent on the overall reaction free energy (ΔG_{13}). The multi-electron mechanisms seem most plausible at very large driving forces, where free energy-reorganization energy matching can occur, and where the larger single-electron-transfer matrix element is offset by a large single-electron activation energy. Tests of these predictions may be accessible in cyclooctatetraene/cyclooctatetraene dianion “mixed-valence” species (Figure 5) in which intramolecular electron exchange has been observed recently [77]. These two-electron processes are known to be sensitive to the counterions present, so construction of species where the dianion charge is compensated in the bridging unit itself is desirable.

Figure 5. Structure of “mixed valence” cyclooctatetraene/cyclooctatetraene dianion species studied by Staley and coworkers [77].

3.4 Conclusions

Many of the issues of current interest in electron-transfer chemistry are associated with complexity that arises from multiple-site hopping (see chapter by Gust, Moore, and Moore), relaxation and dephasing, competing pathways, bridge dynamics, hopping-superexchange transitions, proton-coupled processes (see chapters by Hammes-Schiffer and Nocera), and multi-electron catalysis [78, 79, 80, 81, 82, 83, 84]. The borders between chemical electron transfer and mesoscopic physics are becoming fuzzy, as issues of conductivity quantization, pathway dephasing, single-molecule/single-electron electronic devices come to the fore as well [85]. On the biological side, imaging of redox proteins via STM is becoming possible, and issues of dynamic fluctuations, hopping vs superexchange transport, and transport mechanisms are arising in new contexts [86, 87].

Acknowledgments

The authors thank the fellows of All Souls College, Oxford, for their generous hospitality and for sharing their outstanding wine cellar with us during our visits. DNB thanks the JS Guggenheim Foundation and the Burroughs–Wellcome Fund for additional support. The research at the University of Cyprus is supported by the Cyprus government through the research program “From Strong Interactions to Molecular Recognition: Theoretical and Computational Studies.” In Pittsburgh, the research is supported by grants from the National Science Foundation and the National Institutes of Health. We thank our colleagues and collaborators for their contributions to the research described in this chapter.

4 Electron Transfer at Electrodes and Interfaces

Daniël Vanmaekelbergh

4.1 Scope

In the first part of this century, electrochemical research was mainly devoted to the mercury electrode in an aqueous electrolyte solution. A mercury electrode has a number of advantageous properties for electrochemical research; its surface can be kept clean, it has a large overpotential for hydrogen evolution and both the interfacial tension and capacitance can be measured. In his famous review [1], D. C. Grahame made the firm statement that “*Nearly everything one desires to know about the electrical double layer is ascertainable with mercury surfaces if it is ascertainable at all.*” At that time, electrochemistry was a self-contained field with a natural basis in thermodynamics and chemical kinetics. Meanwhile, the development of quantum mechanics led to considerable progress in solid-state physics and, later, to the understanding of electrostatic and electrodynamic phenomena at metal and semiconductor interfaces.

At present, electrochemical science is a multidisciplinary field overlapping with many other fields, such as solid-state physics and chemistry, surface science, statistical physics including molecular dynamics and quantum chemistry [2, 3, 4]. This opening-up of the field has several origins. The development of device physics, where charged interfaces between various metals and semiconductors played a key role, is an important factor. In addition, the enormous progress in experimental and theoretical investigations of inter- and intramolecular electron-transfer processes has surely promoted fundamentally new developments in electrochemical kinetics [5]. It is now recognized that electrochemical processes may proceed in completely different ways at a molecular level; in some reactions ions are transferred through the electrochemical double layer; in others, electrons tunnel through the double layer without disturbing it.

In this chapter, it is my aim to discuss electrochemical phenomena in a rather general way, starting from basic concepts derived from solid state physics and interfacial science (Sections 4.2 and 4.3). Thus, the electrochemical double layer is

discussed, with, as starting point, the electrical double layer at a metal/vacuum surface (Section 4.5). In Sections 4.8 and 4.9, electrochemical electron transfer is treated in terms of elastic tunneling events between energy levels located at both sides of the interfacial double layer. This procedure is similar to that used to describe interfacial tunneling between two metals in Section 4.6. Such an analogy is made possible if the electron energy levels are defined to correspond to a dissolved redox system; the fluctuating-energy-level model is dealt with in Section 4.4. In Section 4.7, the various mechanisms of electrochemical processes are discussed. It is shown that, at a molecular level, a clear distinction can be made between electrochemical ion transfer and simple electron transfer. In this section, the reason why current-potential characteristics may have common features despite the diversity of mechanisms is also explained. The purely phenomenological treatment is compared with microscopic models for outer-sphere electron transfer in Section 4.8.

4.2 Open Electron Systems

A steady-state current flowing in an electrical device corresponds to a net movement of electrons over macroscopic distances. Since electrical devices consist of more than one phase, there is also a net flux of electrons through the phase boundaries. Transfer of electrons through interfaces forms an important subject in surface physics and chemistry, including electrochemistry. For example, a steady-state current flow in an electrochemical cell consisting of two Pt electrodes and a solution containing the oxidized and reduced species of a redox system means that electrons are transferred from the reduced species to the Pt electrode through the electrochemical double layer at one electrode, and that electrons are transferred from the other Pt electrode to the oxidized species. The current through the solution corresponds to the movement of ions. In electrochemical language, electron flow through the cell is due to a potential difference between the two electrodes. Here, we will use the concept of electrochemical potential to discuss the conditions for electronic equilibrium in one phase and between two phases [6–8]. We also consider electron transport due to a gradient of the electrochemical potential and transfer caused by a drop of the electrochemical potential across an interface. The use of the electrochemical potential makes it easier to discuss electrochemical electron transfer in the more general framework of interfacial electron transfer.

4.2.1 The Electrochemical Potential

We consider a system of N electrons separated from the surroundings by a wall that allows work to be performed on the surroundings and heat to be exchanged. In addition, electrons may enter or leave the system through the wall (i.e., through an interface). Thus, the system is *open* with respect to electrons. The change in the internal energy, U , is accounted for by the so-called central law of thermodynamics:

$$dU = T dS - P dV + \mu dN \quad (1)$$

Here, μ is the chemical potential of the electrons in the system at a given temperature T , P is the pressure, and N is the number of electrons. The chemical potential accounts for the kinetic energy of the electrons and the potential energy due to interactions of the electrons with the other electrons and the core ions. (A microscopic theory for electrons in a solid phase is discussed in Section 4.3.) From Eq. 1 it follows that μ can be defined as the increase in internal energy of the electron system when one electron is added to the system under conditions of constant volume V and entropy S :

$$\mu = \left(\frac{\partial U}{\partial N} \right)_{S, V} \quad (2)$$

A particularly interesting relationship between the chemical potential and the Gibbs free energy, G , is found from Eq. 1 and $G = H - TS = U + PV - TS$:

$$dG = V dP - S dT + \mu dN \quad (3)$$

From Eq. 3 it follows that the chemical potential is equal to the increase in free energy of the electron system upon addition of one electron at constant pressure and temperature:

$$\mu = \left(\frac{\partial G}{\partial N} \right)_{P, T} \quad (4)$$

So far, we have considered open electron systems. We would, however, like to apply the concepts introduced above to electrical and electrochemical devices that consist of metals and/or doped insulators. Solid phases, such as metals and insulators do not contain electrons only. For instance, a metal consists of a regular array of core ions, and more or less freely moving electrons (the electron gas). However, as long as we discuss the transfer or directed motion of solely electrons, the concept of the chemical potential of the electrons in a (solid) phase remains valuable.

In solid state physics and chemistry, and in electrochemistry, an entire phase has often a potential ϕ with respect to a reference potential. The electrons in the entire phase have then an additional potential energy which forms a contribution to the free energy of the electron system. This is clear from the fact that an electron from a given phase, at potential ϕ , may perform work in an external circuit by leaving this phase and arriving in a similar phase at a higher potential. We account for this effect by writing Eq. 4 in a more general form:

$$\mu_e = \left(\frac{\partial G}{\partial N} \right)_{P, T, \phi} = \mu - e\phi \quad (5)$$

Here, μ_e is the electrochemical potential; μ accounts for the kinetic energy and the potential energy due to electron–electron and electron–core-ion interactions (“in-

ternal” contribution); $-e\varphi$ then forms the “external” contribution to the chemical potential. We will see that, in practice, a change in the electrochemical potential of the electrons in a given phase is brought about by a change in the potential energy term $-e\varphi$.

4.2.2 Electronic Equilibrium between Two Phases

We consider a system of two phases in electrical contact. For instance, this system may consist of two pieces of metal so close that electrons can tunnel between the two. In thermodynamic language, we consider a system consisting of two subsystems (A, B) separated by a boundary allowing the passage of electrons. The system is isolated from the surroundings, which means that the total internal energy is constant, that is, $U = U_A + U_B = \text{constant}$. We also assume that the subsystems are in thermal and mechanical equilibrium ($T_A = T_B$, $P_A = P_B$) and that both contain a large number of electrons (Figure 1). Our goal is now to find the condition for equilibrium with respect to electron exchange. If there is no net electron flow from one subsystem to the other, electronic equilibrium is reached and the entropy of the entire system is maximal (Figure 2):

$$S = S_A + S_B = \text{maximal} \quad (6)$$

Figure 1. Two free electron systems separated by an interface through which electrons can be exchanged. (a) Situation before electronic equilibrium: the electrochemical potential in phase A is higher than in B, electrons tunnel from A to B. (b) Electronic equilibrium: the electrochemical potential has the same value in both phases.

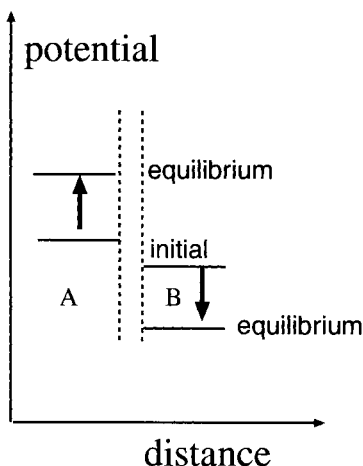

Figure 2. Change of the [electrostatic] potential of both phases due to electron flow from phase A to phase B, during equilibration. The arrows show the change of the potential, which is caused by surface charging.

We consider an infinitesimal deviation from electronic equilibrium, the transfer of a very small number, dN_A , of electrons from subsystem A to B, so that $dS = 0$. From Eq. 1, it follows that

$$0 = dS_A + dS_B = T^{-1}(dU_A + dU_B - \mu_{e,A} dN_A - \mu_{e,B} dN_B) \quad (7)$$

Since $dU_A = -dU_B$, and $dN_A = -dN_B$, it follows, under conditions of thermal and mechanical equilibrium, that electronic equilibrium is reached when the electrochemical potential of the electrons in both subsystems is equal:

$$\mu_{e,A} = \mu_{e,B} \quad (\text{given and constant } T, P) \quad (8)$$

The condition for electronic equilibrium means that there is no *net* flow of electrons from one subsystem to the other. However, there is a flux of electrons from A to B, compensated by a flux from B to A:

$$J_{A \rightarrow B}^{\text{eq}} = J_{B \rightarrow A}^{\text{eq}} = J^{\text{eq}} \quad (9)$$

J^{eq} is the interfacial exchange flux. The exchange flux (or the electrical equivalent, the exchange current density) is an important quantity. Its value is determined by the kinetics of electron exchange between the two phases (Sections 4.6 to 4.9). With a (small) deviation from equilibrium between the two subsystems, a net electron flux from one subsystem to the other occurs and is proportional to J^{eq} . It must be remarked that the condition (Eq. 8) for electronic equilibrium implies that the chemical potential is averaged over a sufficiently long time period. Time-resolved measurements may show fluctuations in the chemical potential around the equilibrium value.

We consider the equilibration between two pieces of metal (A and B) as an example. Before the pieces are in contact, the electrochemical potentials are respec-

tively $\mu_{e,A}$ (initial) and $\mu_{e,B}$ (initial). We assume that $\mu_{e,A}$ (initial) is larger than $\mu_{e,B}$ (initial). The pieces are brought in close contact so that electrons may tunnel from one phase to the other. Electrons are transferred from A to B until equilibrium is reached. At equilibrium $\mu_{e,A}^{\text{eq}}$ is equal to $\mu_{e,B}^{\text{eq}}$. However, the number of electrons which are transferred from A to B is relatively small. It can be assumed that the chemical potential of the electrons in both phases is hardly changed. The change in the electrochemical potential is caused by changes in the potential energy of both phases. Equilibration leads to changes $-e\phi_A$ (initial) \rightarrow $-e\phi_A$ (equilibrium), and $-e\phi_B$ (initial) \rightarrow $-e\phi_B$ (equilibrium) (Figure 2). These changes are due to the fact that a small amount of charge can change the potential of the entire phase considerably. Assume, for instance, that A and B are metallic cubes of 1 cm^3 in volume and 6 cm^2 surface area, and that the surface capacitance C is $10^{-5} \text{ C V}^{-1} \text{ cm}^{-2}$. In Section 4.3, it is shown that such a system contains approximately 10^{22} free electrons. The change of the electrical potential of phase A due to the transfer

of one electron is $d\phi = \frac{1.6 \times 10^{-19}}{C} \text{ V}$, which is $0.3 \times 10^{-14} \text{ V}$. The transfer of the tiny number of 10^{14} electrons from phase A to B ($1.6 \times 10^{-9} \text{ mol}$), results in a 0.3-V increase in the electrical potential of phase A, accompanied by a 0.3-eV decrease in the electrochemical potential. It is clear that the 'internal' chemical potential in the two phases is scarcely changed by the transfer of only 10^{14} of the total number of 10^{22} free electrons. In conclusion, a change in the electrochemical potential of a macroscopic phase is due to a change of the potential energy of the entire phase.

4.2.3 Deviations from Equilibrium

First, we show that electrons *tend* to flow from a region with a higher electrochemical potential to a region with a lower electrochemical potential. We consider a small, but finite departure from the equilibrium situation between the two subsystems A and B; the number of electrons is $N_A^{\text{eq}} + \Delta N$ and $N_B^{\text{eq}} - \Delta N$, respectively ($\Delta N > 0$). The entropy of the isolated system is lower than the equilibrium value. The entropy increases when the system evolves towards equilibrium by the transfer of the small excess of electrons from A to B:

$$\Delta S = T^{-1}[-\mu_{e,A}(-\Delta N) - \mu_{e,B}(\Delta N)] > 0 \quad (10)$$

Hence, it follows that electrons flow from the subsystem A with higher electrochemical potential to subsystem B with lower electrochemical potential.

In many experimental situations, a steady-state *nonequilibrium* condition between two phases (A and B) is sustained by electrical work being done on the system. For instance, the net interfacial electron flux $J_{A \rightarrow B}$ is measured as a function of the difference in the electrochemical potential $\mu_{e,A} - \mu_{e,B}$. For a sufficiently small departure from equilibrium, it is observed that the net flux is proportional to the exchange flux and increases with increasing $|\mu_{e,A} - \mu_{e,B}|$:

$$J_{A \rightarrow B} = J^{\text{eq}} f(\mu_A - \mu_B) \quad (11)$$

There is often a small region around equilibrium in which the net flux is proportional to J^{eq} and $\mu_{e,A} - \mu_{e,B}$. Experimental investigation of the precise relationship between the net current flow and the deviation from equilibrium has been a major issue in interfacial science (Section 4.6). The measurement of the relationship between the interfacial electron flux and the electrochemical potential of the electrons in an electrode, and a fundamental interpretation of it, continue to be important issues in electrochemistry (Sections 4.7 to 4.9).

When a phase is not in electronic equilibrium, electrons tend to flow from a position of higher to a position of lower electrochemical potential. A net directed flow of electrons through the phase occurs, proportional to the gradient in the electrochemical potential [9]. If we consider a phase in which there is a gradient in the electrochemical potential in the x -direction only, the net flux of electrons is given by

$$J(x) = (-1/e)[(k_B T/e)D]n(x) \left[\frac{\partial \mu_e}{\partial x} \right] \quad (12)$$

The electron flux is hence proportional to the density of electrons, $n(x)$, the mobility of the electrons $[(k_B T/e)D]$ (D being the diffusion constant) and the driving force $\left[\frac{\partial \mu_e}{\partial x} \right]$.

For instance, in a photovoltaic or a photoelectrochemical solar cell, a (small) drop in the electrochemical potential over the active phase is necessary for collecting the electrons [6, 9]. However, it leads to a decrease of the work that an electron can perform in the external circuit.

4.3 The Electronic Structure of Solids

In Section 4.2, it was shown that the electrochemical potential is the relevant state function for use in discussions of electronic equilibrium and deviations from equilibrium. Consider, for example, two metal phases (A and B) so close that electrons may tunnel from one phase to the other. The difference in the electrochemical potential of the two phases quantifies the deviation from equilibrium; this difference is very important for the rate of electron transfer. However, it is clear that thermodynamic considerations do not lead to predictions of the rate of electron transfer.

The net interfacial electron flux is the result of many discrete tunneling events between electron levels in phases A and B. Usually, electron tunneling is an elastic process; it occurs between an occupied and an empty electron level of the same energy. Hence, the probability of electron tunneling depends on the distribution of the electron levels at both sides of the interface, and on their occupancy. The electronic structure of solids is thus of primary importance for the kinetics of interfacial electron transfer. In analogy, electrochemical electron transfer can be regarded as the result of discrete tunneling events between electron levels in a solid (the elec-

trode) and the redox system in solution. For dealing with electrochemical electron transfer in a similar way as electron transfer between two solid phases, a model for the electron levels corresponding to a redox system in solution is also required. This subject will be treated in Section 4.4. First, the electronic structure of metals, semiconductors, and insulators will be discussed.

4.3.1 Free and Independent Electrons

Metals form a class of solids with characteristic macroscopic properties. They are ductile, have a silver-white luster, and they conduct electricity and heat remarkably well. An early, but still relevant microscopic model aimed at explaining the electrical conductivity, heat conductivity, and optical properties was proposed by Drude [10]. His model incorporates two important successes of modern science: the discovery of the electron in 1887 by J. J. Thomson, and the molecular kinetic gas theory put forward by Boltzmann and Maxwell in the second half of the 19th century.

Drude assumed that the macroscopic properties of metals are due to an electron gas present in the metallic phase. As in the kinetic model proposed for perfect gases, the electrons do not interact with each other, except during elastic collisions. This is called the independent electron approximation. The density of electrons in a metal is huge, 10^{22} – 10^{23} cm^{-3} , much larger than the molecular density in a perfect gas. Nevertheless, the independent electron approximation has been successfully used in modern quantum mechanical models. Drude furthermore assumed that the distribution of the kinetic energy of individual electrons is given by the Maxwell–Boltzmann distribution, and that the average kinetic energy of the electron gas is therefore $3/2k_B T$. The electrons stay in the solid phase owing to attraction by the positive background charge, which is, according to Drude, smeared out over the entire solid. Hence, the major effect of the positive background charge is to create a potential energy well at the metal surface, keeping the electrons inside (Figure 3).

The modern picture is that we have a lattice of positive core ions and more or less freely moving valence electrons. The moving valence electrons interact with the periodic potential energy field of the core ions, and this interaction must be taken into account for a complete description of the electronic structure of solids (Section 4.3.4). The wave-mechanical interaction between electrons and the lattice of ion cores is a necessary element for the understanding that the energetic distribution of electrons is not a continuous function, but is organized in energy bands, separated by forbidden gaps. The electron–lattice interaction was not incorporated in the Drude model. Even in simple quantum-mechanical models, such as that of Sommerfeld (Section 4.3.2), this interaction is completely ignored. Thus, both the Drude and Sommerfeld models are *free-electron models*, in which the interaction of freely moving valence electrons with the periodic field of core ions is neglected.

The Sommerfeld model is a simple quantum-mechanical model which takes the Pauli principle into account. It is sufficient for developing a model for the probability of electron tunneling events. It will therefore be discussed in some detail in the next section. A more detailed discussion can be found in Ref. [11].

Figure 3. Energy diagram for free electrons in a metal. The positive background charge of the core ions leads to a potential energy well with respect to the energy of the electron in vacuum E_{vac} . The averaged kinetic energy of the free electrons is indicated with dashed lines: $3/2 k_B T$ according to the Drude model, and $3/5 \mu_e$ according to the Sommerfeld model. The electrochemical potential μ_e of the electrons in the metal [Fermi level] is also indicated.

4.3.2 The Sommerfeld Model for Free Electrons in a Metallic Phase

We consider a metallic phase of volume V , with N free electrons, and hence a free electron density n given by $n = N/V$. The charge of the core ions is smeared out and leads to a potential energy well keeping the free electrons in the metallic phase (Figure 3). Since in the Sommerfeld model the electrons do not interact with each other, we can describe the electron energy levels by *one-electron wave functions*. An independent electron can be described by a single-electron wave function $\psi(x, y, z)$ which satisfies

$$\begin{aligned} \frac{-\hbar^2}{2m_e} \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \psi(x, y, z) + E_p(x, y, z) \psi(x, y, z) \\ = E(x, y, z) \psi(x, y, z) \end{aligned} \quad (13)$$

In the free-electron approximation, the potential energy is position-independent; E_p is then an additive constant set here to zero, $E_p = 0$ (Figure 3); the total energy $E(x, y, z)$ is purely kinetic. A solution of Eq. 13 is

$$\psi_{\vec{k}}(\vec{r}) = \frac{1}{\sqrt{V}} e^{i\vec{k} \cdot \vec{r}} = \frac{1}{\sqrt{V}} e^{i(k_x x + k_y y + k_z z)} \quad (14)$$

The vector \vec{k} is the wave vector. The plane wave $e^{i\vec{k}\cdot\vec{r}}$ has a constant amplitude in any plane perpendicular to \vec{k} , and is periodic along lines parallel to \vec{k} , with a wavelength $\lambda = 2\pi/k$. The prefactor $\frac{1}{\sqrt{V}}$ is due to the normalization condition that the electron must be present in the volume V . The total (kinetic) energy of electrons with wave vector \vec{k} is

$$E(\vec{k}) = \frac{\hbar^2 k^2}{2m_e} = \frac{\hbar^2 (k_x^2 + k_y^2 + k_z^2)}{2m_e} \quad (15)$$

The one-electron wave functions $\psi_{\vec{k}}(\vec{r})$ should correspond to propagating rather than standing waves. The mathematical procedure for obtaining propagating waves was developed by Born and von Karman [11]. They considered a cube of volume V with sides L . The electron waves leave the metal through a face of the cube and reenter it simultaneously through the opposite face. The boundary conditions are hence periodic:

$$\left. \begin{aligned} \psi(x, y, z) &= \psi(x + L, y, z) \\ \psi(x, y, z) &= \psi(x, y + L, z) \\ \psi(x, y, z) &= \psi(x, y, z + L) \end{aligned} \right\} \quad (16)$$

The wave function presented by Eq. 14 is in accordance with the boundary condition (Eq. 16) if, $e^{ik_x L} = 1$ etc., hence if

$$\left. \begin{aligned} k_x &= m_x(2\pi/L) & m_x &= 0, \pm 1, \pm 2, \dots \\ k_y &= m_y(2\pi/L) & m_y &= 0, \pm 1, \pm 2, \dots \\ k_z &= m_z(2\pi/L) & m_z &= 0, \pm 1, \pm 2, \dots \end{aligned} \right\} \quad (17)$$

The free-electron levels described by Eqs. 15–17 can be represented in the three-dimensional k space (Figure 4). From this figure and Eq. 15 it is clear that the number of electron levels with a given energy E increases considerably with increasing E .

The occupation of the electron levels is in accordance with the Pauli exclusion principle. Two electrons per $\vec{k}(k_x, k_y, k_z)$ vector are allowed, with opposite spin. The electron levels are filled in order of increasing energy, beginning with the level of lowest energy ($E = 0$). Since we deal with a huge number of electrons, the occupied volume in k -space will form a sphere with radius k_F ; the corresponding energy is the Fermi energy $E_F = \frac{\hbar^2 k_F^2}{2m_e}$ (Figure 4). The number of electrons is equal to twice the number of k points within the sphere, hence

$$N(E \leq E_F) \equiv N = 2 \frac{(4/3)\pi k_F^3}{(2\pi/L)^3} = \frac{k_F^3}{3\pi^2} V \quad (18)$$

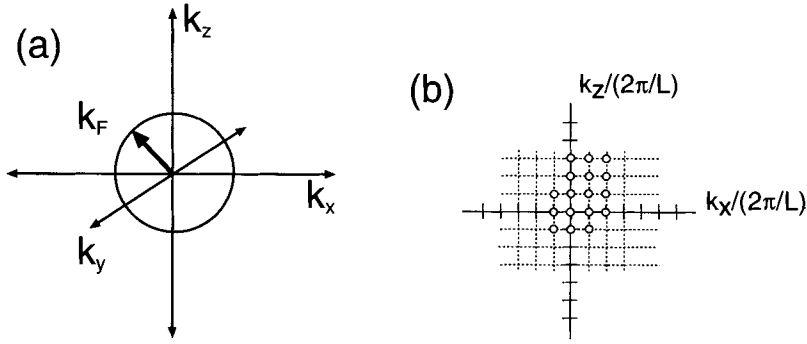

Figure 4. (a) The Fermi surface in k -space according to the free electron model of Sommerfeld. (b) The allowed free electron states are represented by discrete points (k_x, k_y, k_z) . The electrons with the highest kinetic energy are on the Fermi-surface.

The free electron density is therefore

$$n = N/V = \frac{k_F^3}{3\pi^2} \quad (19)$$

Another important quantity is the density of electron-energy levels in a small energy region between E and $E + dE$. It is found by calculation of the number of allowed k values in a shell of k -space between k and $k + dk$, being $\frac{4\pi k^2 dk}{(2\pi/L)^3}$, division by the volume, substitution of k by E in Eq. 15, and multiplication by two to account for the electron spin. The result is that the density of energy levels between E and $E + dE$ is given by

$$g(E) dE = \frac{\sqrt{2}m_e^{3/2}}{\pi^2\hbar^3} E^{1/2} dE \quad (20)$$

The average kinetic energy of a free electron follows from Eqs. 15, 19, and 20:

$$\langle E_k \rangle = \int_0^{E_F} g(E) E dE / n = 3/5 E_F \quad (21)$$

This result can be understood qualitatively by examination of Figure 4: a large fraction of the free electrons are located close to the Fermi surface. It is of interest to compare the average kinetic energy, $3/5 E_F$, with the average kinetic energy $3/2 k_B T$ of particles in the classical Maxwell-Boltzmann distribution, which was used by Drude (Figure 13). Using Eqs. 18 and 15, we can express E_F as a function of the free-electron density n . The free-electron density in most metals is between 10^{22} and 10^{23} cm^{-3} . This gives a Fermi energy of between 1.5 and 5 eV. The aver-

age kinetic energy in the Sommerfeld model is hence much larger than $3/2k_B T$ in the entire temperature range from 0 K up to room temperature.

4.3.3 Occupation of the Electron-Energy Levels

The distribution of the electron levels, $g(E)$, for a gas of independent and free electrons was calculated in the foregoing section. At 0 K, all energy levels up to the Fermi-energy level are occupied with one electron. (The spin degeneracy was accounted for in the density $g(E)$.) From the definition of chemical potential given in Section 4.2.1, $\mu = \left(\frac{\partial U}{\partial N} \right)_{S,V}$, it directly follows that the Fermi-level E_F is equal to the chemical potential μ at $T = 0$ K (and $\varphi = 0$). It can be shown quantitatively that this is true as long as $k_B T \ll E_F$ [11].

The occupation of the electron energy levels under thermal equilibrium at $T > 0$ K can be derived from statistical thermodynamics [11]. The reasoning results in the well-known Fermi–Dirac occupation function. The probability that an electron energy level at E is occupied by an electron is given by

$$f(E) = \frac{1}{1 + e^{(E - \mu_e)/k_B T}} \quad (22)$$

In the energy region $\mu_e - k_B T < E < \mu_e + k_B T$, there is a smooth transition from $f \approx 1$ to $f \approx 0$. In Figure 5, $g(E)f(E)$ is sketched for a free-electron gas.

When we add an electron to the system at a given temperature and pressure, the electron is necessarily positioned in a level close to μ_e . The increase in free energy of the electron system due to the addition of one electron is hence μ_e (Figure 5). Hence, the Fermi–Dirac occupation function is in accordance with the thermodynamic definition of the electrochemical potential.

4.3.4 The Origin of Energy Bands

In the free-electron model, the interaction of valence electrons with the lattice of core ions is neglected. As a result, the energy of the electrons varies in a continuous way with the wave vector \vec{k} (Eq. 15). Here, we discuss in a rather qualitative way how the $E(k)$ relationship is affected by the interaction of the electron waves with the periodic lattice. For simplicity, we consider electrons moving in the (positive) x

direction, hence with wave vectors $k_x = \frac{2\pi}{(L/m_x)}$ (Eq. 17) and corresponding wave-

lengths $\lambda = \frac{2\pi}{k_x} = \frac{L}{m_x}$. The distance between the centers of the core ions in the x direction is denoted by d_x . There is, hence, a modulation of the potential energy in the x direction, given by

$$E_p(x) = E_p(\text{max}) \cos(2\pi x/d_x) \quad (23)$$

Figure 5. The density of electron states, $g(E)$, (dashed line), and the density of occupied states, $g(E)f(E)$, (full line, $T > 0$ K) as a function of the energy, according to the free electron model of Sommerfeld.

(Similar modulations hold for the y and z directions.) The electrons with low energy have wavelengths much larger than the lattice constant d_x . However, at higher energy there are free electrons with wavelengths obeying

$$\frac{\lambda}{2} \cong q \times d_x \quad (q = 1, 2, \dots) \quad (24)$$

Such electrons will be reflected backward and forward between two (adjacent) core ions (Bragg reflection). Due to the periodic lattice, electron propagation is prohibited in the x direction when the wave vector is equal (or close) to $k_x = \frac{2\pi}{\lambda} = \frac{\pi}{q \times d_x}$. This is also true for electrons moving in the negative x direction,

with $k_x = -\frac{\pi}{q \times d_x}$. Thus, propagating waves are prohibited because of Bragg reflection whenever

$$k_x = \pm \frac{\pi}{q \times d_x} \quad (q = 1, 2, \dots) \quad (25)$$

Electrons undergoing Bragg reflection correspond to standing waves. Two standing waves can be constructed by a linear combination of the waves propagat-

Figure 6. Sketches of the relationship between the energy E and wave vector k , when electron scattering with the periodic lattice is taken into account. (a) Nearly free electrons: the scattering is relatively weak, the free electron model is approximately valid for $k < \pi/d$. (b) Strong interaction: the free electron model is not valid. Tiny bands are separated by broad band gaps.

ing in the positive and negative x directions. The electron density corresponding to the first standing wave is centered at the core ions; the electron density corresponding to the second one is between the core ions. The two standing waves correspond to considerably different energies. With perturbation theory, it can be shown that the energy difference is equal to the amplitude of the periodic perturbation in the x direction, that is, $E_p(\text{max})$ (see Eq. 23).

It is concluded that scattering of the free-electron waves at the periodic lattice potential leads to discontinuities in the $E(k)$ relationship at k values of around

$k = \pm \frac{\pi}{q \times d}$ ($q = 1, 2, \dots$). Energy bands, separated by gaps, are formed. The first

and second energy bands, separated by a gap, are shown in Figure 6. A more elaborate treatment shows that the width of the energy bands and gaps is determined by the strength of the interaction between the valence electrons and the core ions. If the interaction is relatively weak, the energy bands extend over a large energy region (several eV), and the energy gaps are narrower than the energy bands [nearly free electrons, see Figure 6(a)]. The $E(k)$ relationship for free electrons holds

for most of the electrons in a band, except near $k = \pm \frac{\pi}{q \times d}$ ($q = 1, 2, \dots$). In

contrast, a strong interaction between valence electrons and core ions results in narrow bands, separated by broad gaps [Figure 6(b)]. The energy of the electrons increases with increasing value of k , with a much lower slope than for free electrons.

The acceleration of valence electrons due to an external force can be discussed with Newton's law ($\vec{a} = \vec{F}/m$), provided that the mass of an electron, m_e , is replaced by the effective mass, m_e^* , of an electron with given energy in a given lattice. It is found that

$$m_e^* = \hbar^2 / (d^2 E / dk^2) \quad (26)$$

From Eqs. 15 and 26 it is clear that the effective mass of free electrons is equal to the real mass. Comparison of Figures 6(a) and (b) shows that electrons strongly bound to the core ions have a larger effective mass than the (nearly) free electrons. This means that the lattice attenuates the response of electrons to an external force, in the same way that a viscous liquid moderates the movement of dissolved particles. However, close to $k = \pm \frac{\pi}{q \times d}$ ($q = 1, 2, \dots$), that is, at the top and bottom of the energy bands, quantum-mechanical features occur which have no classical counterpart. The effective mass of the electrons can be much larger and much smaller than the real mass, and can, indeed, be negative.

4.3.5 Metals, Semiconductors and Insulators

The energy levels at 0 K are filled in accordance with the Pauli principle, starting at $E = 0$. Two major classes of solids can be distinguished. When an energy band is not completely filled, the Fermi energy (chemical potential) is located in a band. There are empty electron levels available directly above the Fermi energy (Figure 5). This means that all electrons in such a band can respond to an external force (electric field) by increase of their kinetic energy. The electrical conductivity, which is the current density divided by the electrical field, is huge; this is the case of a metal. When filling of the electron levels leads to completely full energy bands, the Fermi energy lies in the gap between the highest occupied band (valence band, VB, top of the band denoted as E_{VB}) and lowest unoccupied band (conduction band, CB, bottom of the band denoted as E_{CB}). The electrons of the full valence band cannot increase their kinetic energy. The electronic conductivity is zero at 0 K, this is the case of an insulator [Figure 7(a)].

When $T > 0$ K, the population of the electron energy levels is described by the Fermi–Dirac distribution function (See Section 4.3.3, Eq. 22). At $T > 0$ K, electrons from the valence band can be thermally excited into the conduction band. As a result, the bottom of the CB becomes partly populated and the top of the VB partly depopulated [Figure 7(b)]. An empty electron level at the top of the valence band is called a (*valence-band*) *hole*. The concentration of holes, p , and of electrons, n , can be expressed as a function of the electrochemical potential with Eq. 22. We denote the density of electron levels within $k_B T$ from the top of the VB and the bottom of the CB as the effective density of valence band levels, N_{VB} , and conduction band levels, N_{CB} , respectively. The electron occupancy of the electron levels at the bottom of the CB is

$$f(E_{CB}) = \frac{n}{N_{CB}} = \frac{1}{1 + e^{(E_{CB} - \mu_e)/k_B T}} \cong e^{-(E_{CB} - \mu_e)/k_B T} \quad (27)$$

The density of holes at the top of the valence band is

$$\frac{p}{N_{VB}} = 1 - f(E_{VB}) = \frac{e^{(E_{VB} - \mu_e)/k_B T}}{1 + e^{(E_{VB} - \mu_e)/k_B T}} \cong e^{(E_{VB} - \mu_e)/k_B T} \quad (28)$$

In deriving Eqs. 27 and 28, it is assumed that $E_{CB} - \mu_e \gg k_B T$ and $\mu_e - E_{VB} \gg k_B T$.

Figure 7. Sketch of the density of electron states as a function of energy for a typical intrinsic semiconductor or insulator. (a) 0 K; (b) $T > 0$ K, some electrons from the valence band are thermally excited into the conduction band in agreement with the Fermi-Dirac function. The electrochemical potential or Fermi level is located in the middle of the gap.

From Eqs. 27 and 28 it also follows that

$$\frac{np}{N_{CB}N_{VB}} = e^{-(E_{CB}-E_{VB})/k_B T} \quad (29)$$

The density of free electrons and holes is determined by the energy gap $E_{CB} - E_{VB}$ and the temperature. Solids for which $E_{CB} - E_{VB}$ is not larger than, say, $10 k_B T$ are often called intrinsic semiconductors. If the gap is much larger, the solids are classified as insulators. The distinction between intrinsic semiconductors and insulators is only quantitative.

4.3.6 Extrinsic Semiconductors

The incorporation of foreign atoms into an otherwise pure solid has important consequences for the optical and electronic properties. Here, we discuss how the electronic structure of insulators is affected by foreign atoms. Incorporation of foreign atoms usually leads to localized electron levels. A considerable effect on the opto-electronic properties is expected, when the localized levels are located in the gap between the VB and CB. For instance, P atoms can be incorporated into pure Si. This leads to localized levels just below E_{CB} . At 0 K, these levels are occupied with an electron [Figure 8(a)]. At room temperature, the localized electrons are easily excited into the CB. The density of free electrons is then approximately equal to the density of P atoms. Equations 27 to 29 are still valid. It is clear that doping of Si with P leads to a considerable increase in the electrochemical potential, which is now not far below E_{CB} [Figure 8(b)]. Doping of Si with P leads to an extrinsic *n*-type semiconductor, for which it holds that $n \gg p$. In contrast, doping of Si with Al (an atom with three valence electrons) leads to a *p*-type extrinsic semiconductor, whereby $p \gg n$ [Figure 9(a),(b)].

Figure 8. Sketch of the density of electron states as a function of energy for a typical *n*-type extrinsic semiconductor. (a) 0 K, the donor atoms correspond to localized filled states just below the conduction band edge; (b) $T > 0$ K, each donor atom is thermally ionized, this leads to a considerable density of electrons at the bottom of the CB; the electrochemical potential is not far below the CB edge.

Figure 9. Sketch of the density of electron states as a function of energy for a typical *p*-type extrinsic semiconductor. (a) 0 K, the acceptors correspond to localized empty states just below the conduction band edge; (b) $T > 0$ K, each acceptor atom is thermally occupied with an electron from the valence band, this leads to a considerable density of holes at the top of the valence band. The electrochemical potential is not far above the VB edge.

4.4 Electron-Energy Levels Corresponding to a Redox System

An important subject in this chapter on “Electron transfer at electrodes and interfaces” is to draw an analogy between electrochemical and interfacial electron transfer between two solid phases. Any theory dealing with electron transfer has a thermodynamic and a kinetic basis. In Section 4.2, it was shown that electrons flow or tunnel in the direction of decreasing electrochemical potential; the gradient of the electrochemical potential is the driving force behind a directed flow of electrons,

through a phase or across an interface. A net interfacial current density is the result of many elastic tunneling events between discrete electron levels on both sides of the interface. Thus, a kinetic treatment requires knowledge of the energetic distribution of electron levels, and their occupancy. Crystalline phases have been discussed in Section 4.3. Here, in Section 4.4.1, we will define the electrochemical potential of a dissolved redox system. Following the seminal work of Gerischer [12], we will discuss, in Section 4.4.2, how one can define the distribution of the empty and occupied electron energy levels corresponding to the oxidized and reduced species, respectively.

4.4.1 The Electrochemical Potential of a Dissolved Redox System

Electron transfer between oxidized and reduced species present in a liquid phase (water) is one of the simplest chemical processes. For instance,

and

In the equilibrium of Eq. 30, electrons are exchanged between the reduced species $\text{Fe}^{2+}(\text{aq})$ and the oxidized species $\text{Fe}^{3+}(\text{aq})$, and vice versa. Exchange occurs under conditions of chemical equilibrium; the reaction free energy ΔG_R is zero. In the second case, a mixture of $\text{Fe}^{2+}(\text{aq})$ and $\text{Ce}^{4+}(\text{aq})$ will spontaneously evolve to an equilibrium mixture of the oxidized and reduced species of both redox systems. The driving force, that is, the reaction free energy at any time is given by

$$\Delta G_R = N_A \{ [\mu(\text{Ce}^{3+}) - \mu(\text{Ce}^{4+})] - [\mu(\text{Fe}^{2+}) - \mu(\text{Fe}^{3+})] \} \quad (32)$$

where the chemical potentials of the reduced and oxidized species are defined per molecule, and ΔG_R is given per mole.

We can devise a galvanic cell, with two inert metal electrodes in two compartments, connected by a salt bridge in which the reaction shown in Eq. 31 evolves electrochemically. The metal electrode in the right compartment is in contact with a solution containing $\text{Fe}^{2+}(\text{aq})$ and $\text{Fe}^{3+}(\text{aq})$ ions, the other one is in contact with $\text{Ce}^{4+}(\text{aq})$ and $\text{Ce}^{3+}(\text{aq})$. A voltmeter will indicate a potential difference between the two electrodes. When they are connected by a wire (external circuit), electrons will flow from the left electrode through the external circuit to the right electrode, until equilibrium is reached. A galvanic cell allows one to monitor the chemical reaction under (nearly) reversible conditions (low rate of the reaction), if a variable resistance (load) in the external circuit is used. It is then reasonable to assume that the electrons in the left and right electrode are in equilibrium with the $\text{Fe}^{2+}(\text{aq})$, $\text{Fe}^{3+}(\text{aq})$ and $\text{Ce}^{4+}(\text{aq})$, $\text{Ce}^{3+}(\text{aq})$ redox system, respectively:

$$\mu_e(\text{left}) = \mu(\text{Fe}^{2+}) - \mu(\text{Fe}^{3+}) \quad (33)$$

$$\mu_e(\text{right}) = \mu(\text{Ce}^{3+}) - \mu(\text{Ce}^{4+}) \quad (34)$$

The reaction free energy ΔG_R is hence directly related to the electrochemical-potential difference measured between the two metal electrodes with a voltmeter (see Eqs. 32–34). Furthermore, the electrochemical potential of a redox system in solution is probed by measurement of the potential of a metal phase, in equilibrium with the redox system, with respect to a reference electrode.

We denote an electrochemical reaction more generally as

The forward process describes the transfer of an electron from a reduced species, which is in equilibrium with the solvent molecules, to a metal phase, with electrochemical potential μ_e ; this results, eventually, in an oxidized species in equilibrium with the solvent molecules. When electronic equilibrium is reached between the metallic phase and the solution, the electrochemical potential in both phases is equal and given by

$$\begin{aligned} \mu_e(\text{Ox/Red}) &= \mu(\text{Red}) - \mu(\text{Ox}) \\ &= [\mu^o(\text{Red}) - \mu^o(\text{Ox})] + k_B T \ln(c_{\text{Red}}/c_{\text{Ox}}) \end{aligned} \quad (36)$$

where the superscript indicates the standard state. Equation 36 is known as the Nernst equation.

4.4.2 The Fluctuating-Energy-Level Model Proposed by Gerischer

In Figure 10, the gradual solvation of the reduced and oxidized forms of a redox system is represented by plots of the potential energy of the ions as a function of a generalized solvation coordinate ρ . Figure 10(a) shows an overview, and (b) is more detailed. Roughly, ρ indicates the distance between the redox ions and the polar solvent molecules. The lower plot shows the potential energy of a the reduced species (Red) as a function of ρ , following

The energy of the reduced species is at a minimum when the equilibrium solvation structure $\text{Red}[\text{solv. Red}]$ is reached; this is characterized by $E_{\text{Red}}^{\text{eq}}$, $\rho = \rho_{\text{Red}}^{\text{eq}}$. The upper curve shows the potential energy of an electron in vacuum and the oxidized species which is gradually solvated:

The equilibrium structure of the solvated oxidized species is indicated as $\text{Ox}[\text{Solv. Ox}]$; the minimum energy and corresponding characteristic value of the solvation

Figure 10a. Solvation curves of the reduced (Red) and Oxidized (Ox) species of a redox system. The potential energies of Red and Ox (+ one electron in vacuum) are shown as a function of a generalized solvation coordinate ρ . I is the ionization energy in the gas phase; $I(\rho)$ is the ionization energy for a given solvation structure. The energy of a solvation structure with respect to equilibrium is indicated by $[E(\rho) - E^{\text{eq}}]$; $E_{\text{Red}}^{\text{eq}}$, and $E_{\text{Ox}}^{\text{eq}}$ correspond to equilibrium solvation. The marks on the potential energy axis are separated by 10 eV.

potential energy

Figure 10b. Detail of Fig. 4.1 (a) showing a thermodynamic cycle involving ionization and solvent reorganization. $I(\rho_{\text{Red}}^{\text{eq}})$ is the ionization energy of the reduced species with an equilibrium solvation structure; $-I(\rho_{\text{Ox}}^{\text{eq}})$ is the electron affinity for the oxidized species with an equilibrium solvation structure. λ is the reorganization energy.

coordinate is denoted as $E_{\text{Ox}}^{\text{eq}}$ and $\rho_{\text{Ox}}^{\text{eq}}$, respectively. The solvation energy of an ion is proportional to the square of the charge of the ion and the inverse of the ion radius [8]. Solvation enthalpies can also be measured experimentally. For example, the solvation energies of the Fe^{2+} and Fe^{3+} ions in water are 20 and 45 eV, respectively.

Due to thermal movement of the solvent molecules in the solvation shell, the potential energy of the reduced and oxidized species may deviate from their equilibrium value. If we could probe the energy of an individual species over a sufficiently long time period, we would find a distribution in its energy around the minimum. The probability that the energy of the oxidized and reduced species deviates from the equilibrium value by $E(\rho) - E^{\text{eq}}$ is given by the Boltzmann distribution:

$$W_{\text{Ox}}(E - E_{\text{Ox}}^{\text{eq}}) = \frac{e^{-[E - E_{\text{Ox}}^{\text{eq}}]/k_B T}}{\int_0^\infty e^{-[E - E_{\text{Ox}}^{\text{eq}}]/k_B T} d(E - E_{\text{Ox}}^{\text{eq}})} \quad (39)$$

$$W_{\text{Red}}(E - E_{\text{Red}}^{\text{eq}}) = \frac{e^{-[E - E_{\text{Red}}^{\text{eq}}]/k_B T}}{\int_0^\infty e^{-[E - E_{\text{Red}}^{\text{eq}}]/k_B T} d(E - E_{\text{Red}}^{\text{eq}})} \quad (40)$$

The merit of Gerischer's early paper [12] is that he found a way to express these probabilities as a function of the electronic energy, whereby the standard electrochemical potential acts as a reference point. The reasoning is as follows. First, the ions in the gas phase ($\rho \rightarrow \infty$) are considered: the energy difference between the two curves is the ionization energy, I , of the reduced ion. For example, the ionization energy for $\text{Fe}^{2+}(\text{g})$ to $\text{Fe}^{3+}(\text{g})$ is 30.6 eV per ion. More generally, the vertical energy difference between the solvation curves, that is, $E[\text{Ox}(\rho) + e_{\text{Vac}}] - E_{\text{Red}}(\rho)$, is the ionization energy $I(\rho)$ of the reduced species at a given nonequilibrium solvation. In this ionization process, the nuclear coordinates remain unchanged (Franck-Condon principle). Gerischer used the vertical energy difference $-I(\rho)$ as an independent variable for further considerations. We denote

$$-I(\rho) = E_{\text{Red}}(\rho) - E_{\text{Ox}}(\rho) - E_{\text{Vac}} \quad (41)$$

Since there is a unique and continuous relationship between $-I(\rho)$ and the solvation coordinate ρ , there is also a unique and continuous relationship between the thermal deviations from equilibrium $[E_{\text{Ox}}(\rho) - E_{\text{Ox}}^{\text{eq}}$ and $E_{\text{Red}}(\rho) - E_{\text{Red}}^{\text{eq}}$] and $-I(\rho)$. This means that the probability of nonequilibrium solvation can be expressed as a function of the vertical energy difference $-I(\rho)$:

$$\left. \begin{aligned} W_{\text{Ox}}(E - E_{\text{Ox}}^{\text{eq}}) &\Rightarrow W_{\text{Ox}}[-I(\rho)], \\ \text{and} \\ W_{\text{Red}}(E - E_{\text{Red}}^{\text{eq}}) &\Rightarrow W_{\text{Red}}[-I(\rho)] \end{aligned} \right\} \quad (42)$$

To find a reference point on the $-I(\rho)$ coordinate axis, we consider the following

equilibrium:

If we compare the electrochemical equilibrium at a metal (Eq 36) with the equilibrium of Eq. 43, we see that in the latter the electron is promoted from the Fermi level in the metal to vacuum by an amount of work equal to the work function being performed, that is, $E_{\text{vac}} - \mu_e^o(\text{Ox/Red})$. Under standard conditions, it holds that, $\mu(e_{\text{vac}}^-) + \mu^o(\text{Ox, solv. Ox}) - \mu^o(\text{Red, solv. Red}) = 0$, and hence that

$$\mu(e_{\text{vac}}^-) = \mu^o(\text{Ox/Red}) + [E_{\text{vac}} - \mu^o(\text{Ox/Red})] \quad (44)$$

The energy difference $E_{\text{Red}}^{\text{eq}} - [E_{\text{Ox}}^{\text{eq}} + E_{\text{vac}}]$ corresponds to $\mu^o(\text{Red, solv. Red}) - \mu^o(\text{Ox, solv. Ox})$, hence to $\mu_e^o(\text{Ox/Red})$ on the electrochemical potential scale. The standard electrochemical potential of the redox system, $\mu_e^o(\text{Ox/Red})$, which is located by amount of energy given by $E_{\text{vac}} - \mu_e^o(\text{Ox/Red})$ below the vacuum level, forms the characteristic reference point (see Figure 12 further on). Inspection of Figure 10(a),(b) shows that

$$[E_{\text{Red}}(\rho) - E_{\text{Red}}^{\text{eq}}] + I(\rho) = [E_{\text{Ox}}(\rho) - E_{\text{Ox}}^{\text{eq}}] + [E_{\text{Ox}}^{\text{eq}} - E_{\text{Red}}^{\text{eq}}] \quad (45a)$$

Two special cases of this general relationship are also important. The first one holds for the discrete case that $\rho = \rho_{\text{Red}}^{\text{eq}}$:

$$I(\rho_{\text{Red}}^{\text{eq}}) = [E_{\text{Ox}}(\rho_{\text{Red}}^{\text{eq}}) - E_{\text{Ox}}^{\text{eq}}] + [E_{\text{Ox}}^{\text{eq}} - E_{\text{Red}}^{\text{eq}}] \quad (45b)$$

The second relationship holds for the case that $\rho = \rho_{\text{Ox}}^{\text{eq}}$:

$$[E_{\text{Red}}(\rho_{\text{Ox}}^{\text{eq}}) - E_{\text{Red}}^{\text{eq}}] + I(\rho_{\text{Ox}}^{\text{eq}}) = [E_{\text{Ox}}^{\text{eq}} - E_{\text{Red}}^{\text{eq}}] \quad (45c)$$

The energy difference $[E_{\text{Ox}}(\rho_{\text{Red}}^{\text{eq}}) - E_{\text{Ox}}^{\text{eq}}]$ is the heat output when the solvation structure around the oxidized species is reorganized, starting from the equilibrium solvation structure typical for the reduced species and ending with the equilibrium structure typical for the oxidized species. $[E_{\text{Red}}(\rho_{\text{Ox}}^{\text{eq}}) - E_{\text{Red}}^{\text{eq}}]$ has an analogous meaning for reorganization around the reduced species. The difference between the values of $[E_{\text{Ox}}(\rho_{\text{Red}}^{\text{eq}}) - E_{\text{Ox}}^{\text{eq}}]$ and $[E_{\text{Red}}(\rho_{\text{Ox}}^{\text{eq}}) - E_{\text{Red}}^{\text{eq}}]$ is small. For simplicity, it is assumed in the literature that they are equal. These reorganization energies are both denoted as λ :

$$\lambda = [E_{\text{Ox}}(\rho_{\text{Red}}^{\text{eq}}) - E_{\text{Ox}}^{\text{eq}}] = [E_{\text{Red}}(\rho_{\text{Ox}}^{\text{eq}}) - E_{\text{Red}}^{\text{eq}}] \quad (46)$$

In Figure 11, the thermal energies of nonequilibrium solvation $[E_{\text{Red}}(\rho) - E_{\text{Red}}^{\text{eq}}]$ and $[E_{\text{Ox}}(\rho) - E_{\text{Ox}}^{\text{eq}}]$ are presented as a function of the vertical energy difference (the y axis). It is clear that $[E_{\text{Red}}(\rho) - E_{\text{Red}}^{\text{eq}}]$ is zero at $-I(\rho_{\text{Red}}^{\text{eq}})$, that $[E_{\text{Ox}}(\rho) - E_{\text{Ox}}^{\text{eq}}]$ is zero at $-I(\rho_{\text{Ox}}^{\text{eq}})$, and that $[E_{\text{Red}}(\rho) - E_{\text{Red}}^{\text{eq}}]$ equals $[E_{\text{Ox}}(\rho) - E_{\text{Ox}}^{\text{eq}}]$ at the reference point $E_{\text{Red}}^{\text{eq}} - E_{\text{Ox}}^{\text{eq}}$, that is, at $\mu_e^o(\text{Ox/Red})$ (see Eqs. 45). In Figure 12, the proba-

Figure 11. Plot of the thermal activation energy corresponding to non-equilibrium solvation $[E(\rho) - E^{\text{eq}}]$ of the oxidized and reduced species (horizontal axis) as a function of the ionization energy $[E_{\text{Red}}(\rho) - E_{\text{Ox}}(\rho)]$. The plot is derived from Fig. 4.1. (see section 4.2). λ is the reorganization energy of the outer sphere redox system.

Figure 12. Sketch of the probabilities $W_{\text{Ox}}(E)$ and $W_{\text{Red}}(E)$ to find an empty or filled electron level corresponding to an oxidized and reduced ion, respectively, as a function of the electron free energy (vertical axis). The standard electrochemical potential $\mu^{\circ}(\text{Ox/Red})$ with respect to the vacuum level acts as a reference point.

bilities $W_{\text{Ox}}[-I(\rho)]$ and $W_{\text{Red}}[-I(\rho)]$ are sketched in a qualitative way (using Eqs. 39–40 and Figure 11). It is clear that $W_{\text{Ox}}[-I(\rho)]$ and $W_{\text{Red}}[-I(\rho)]$ have their maximum at $-I(\rho_{\text{Ox}}^{\text{eq}})$ and $-I(\rho_{\text{Red}}^{\text{eq}})$, respectively, and that the probabilities are equal at $\mu_e^o(\text{Ox/Red})$. From Eq. 45c, it follows that $-I(\rho_{\text{Ox}}^{\text{eq}})$ is located at $[E_{\text{Red}}^{\text{eq}} - E_{\text{Ox}}^{\text{eq}}] + [E_{\text{Red}}(\rho_{\text{Ox}}^{\text{eq}}) - E_{\text{Red}}^{\text{eq}}]$, that is, an energy λ above $\mu_e^o(\text{Ox/Red})$. Similarly, it follows from Eq. 45b that the maximum of $W_{\text{Red}}[-I(\rho)]$ is located at λ below $\mu_e^o(\text{Ox/Red})$.

The foregoing discussion makes it clear that the vertical energy difference $-I(\rho)$ forms an electronic energy coordinate axis with a characteristic reference point, $\mu_e^o(\text{Ox/Red})$, which is experimentally accessible. This means that the probability functions can be used directly in models for electrochemical electron transfer between a solid and a simple redox system (see Sections 4.8 and 4.9). In the literature, the electronic energy coordinate axis has been denoted as E , and the characteristic points as $\mu_e^o(\text{Ox/Red})$ (or E_F^o), and E_{Ox}^m and E_{Red}^m denoted the energies corresponding to the maximum $W_{\text{Ox}}(E)$ and $W_{\text{Red}}(E)$ values, respectively. For quantitative purposes (see Sections 4.8 and 4.9), the probability functions are expressed as normalized Gauss functions:

$$W_{\text{Ox}}(E) = (4\pi k_B T \lambda)^{-1/2} e^{-(E - E_{\text{Ox}}^m)^2 / 4\lambda k_B T} \quad (47)$$

and

$$W_{\text{Red}}(E) = (4\pi k_B T \lambda)^{-1/2} e^{-(E - E_{\text{Red}}^m)^2 / 4\lambda k_B T} \quad (48)$$

The density of empty and occupied electron-energy levels corresponding to a dissolved redox system are given by

$$g_{\text{Ox}}(E) = W_{\text{Ox}}(E) c_{\text{Ox}} \quad (49)$$

and

$$g_{\text{Red}}(E) = W_{\text{Red}}(E) c_{\text{Red}} \quad (50)$$

respectively. The electrochemical potential of the redox system in solution corresponds to the energy whereby $g_{\text{Ox}}(E) = g_{\text{Red}}(E)$.

4.5 Interfacial Structure

Research dealing with the atomic structure and charge distribution at crystal surfaces is a modern and fast-developing field. Metal and semiconductor surfaces show many interesting features, and this is certainly also the case for electrochemical interfaces, that is, metal (or semiconductor)/(aqueous) solution interfaces. This section is not intended to give a comprehensive overview of surface and interfacial

structures. The aim is to provide a general (but somewhat simplified) picture of electrochemical interfaces, convenient for a further discussion of electrochemical electron transfer. In the last two decades it became clear that the surface structure of the solid is a relevant factor for a better understanding of electrochemical interfaces. Therefore, this surface structure is discussed first. The metal/solution electrochemical interface can then be “constructed” by taking into account physisorption and chemisorption of water and ions.

4.5.1 Metal Surfaces

Crystals are characterized by a regular array of atoms. In the bulk, all atoms are surrounded by their neighbors in the same way. However, atoms at the surface can only interact with each other and the inner neighbors. This results in surface tension, and an inward contraction of the surface atoms (or core ions).

A second surface effect is due to the high kinetic energy and small mass of the free electrons (see Section 4.3). Electrons impinging on the surface wall may penetrate this wall; this decreases their kinetic energy and increases their potential energy. Electrons spill over the surface plane, which corresponds to the center of the core ions. A time-averaged sketch of the distribution of the electrons and ions near the surface of a metal is presented in Figure 13(a).

The free-electron model allows a more quantitative discussion of the probability of finding electrons in a limited region just outside the surface plane. Consider a metal surface in the (y, z) -plane (Figure 14). The potential energy in the crystal is set to zero. The potential energy of an electron at rest, outside the metal is denoted as E_{vac} . It is clear that the Fermi energy, E_F , of the electrons is considerably below E_{vac} ; the work function $E_{\text{vac}} - \mu_e$ is generally in the order of a few eV. From Eqs. 13–14 it follows that the component of the wave functions in the x direction is given by

$$\psi(x) = \frac{1}{\sqrt{L}} e^{ik_x x} \quad (51)$$

and the corresponding kinetic energy is by given

$$E(k_x) = \frac{\hbar^2 k_x^2}{2m_e} \quad (52)$$

The Schrödinger equation for the region outside the metal is

$$\frac{-\hbar^2}{2m_e} \frac{\partial^2 \psi(x)}{\partial x^2} + E_{\text{vac}} \psi(x) = E(x) \psi(x) \quad (53)$$

It is important to note that the energy of the electron in rest in vacuum, E_{vac} , is larger than the total energy of the impinging electron. Nevertheless, wave functions

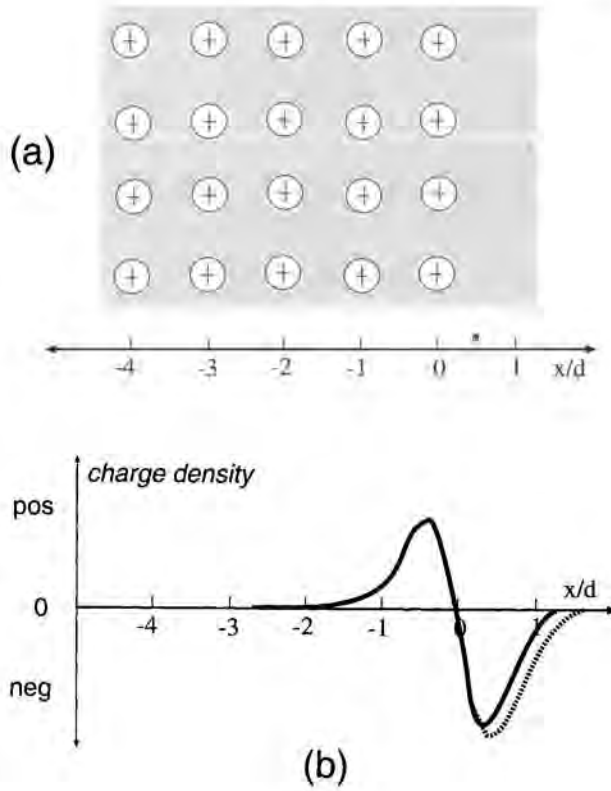

Figure 13. Schematic representation of the double layer at a metal surface. (a) Lattice of positive core ions (lattice parameter is d), the electron density is indicated with grey; electrons spill over the jellium plane (at $x/d = 0$). (b) Charge density, roughly corresponding to the jellium model. Just inside the metal, the charge density is positive, the spill-over region has a negative charge. The dashed line indicates the charge density when there is a net negative surface charge.

Figure 14. Free electron wave function corresponding to an electron moving in the x -direction, perpendicular to the surface. The dashed line shows the exponential decay of the wave function in vacuum; the decay length being $1/\kappa_{\text{vac}}$.

of the form

$$\psi_{\text{vac}}(x) = \frac{1}{\sqrt{L}} e^{-\kappa_{\text{vac}} x} \quad (54)$$

with

$$\kappa_{\text{vac}}(x) = \left[\frac{2m_e [E_{\text{vac}} - E(x)]}{\hbar^2} \right]^{1/2} \quad (55)$$

are solutions of Eq. 53. The wave functions of electrons impinging on the surface decay exponentially outside the metal. The decay length $1/\kappa_{\text{vac}}$ depends on the effective barrier height $E_{\text{vac}} - E(x)$. From Eq. 55, it follows that the decay length $1/\kappa_{\text{vac}}$ is 1.9 Å for a barrier height of 1 eV. The exponential decay of wave functions is a key feature in understanding electron tunneling (see Section 4.6). It is furthermore clear that there is a considerable probability of finding free electrons at the other side of the surface plane in a region extending over some unit cells (see also Figure 13).

The electron distribution at metal surfaces has been discussed with more realistic models than the free-electron model being used. The “jellium” model [13] is often used in surface science; it takes into account electron–electron interactions while the charge of the core ions is smeared out homogeneously over the crystal. It also forms a basis for realistic models of the electrochemical double layer [2]. The “jellium” model results in a picture for the double layer at the metal surface which differs from Figure 13 in details only.

The time-averaged situation is sketched in Figure 13(a). In Figure 13b, the charge density is sketched. There is an excess of positive charge just inside the metal and an excess of negative charge just outside the metal surface. Electron spill-over gives rise to an electrical double layer at the metal surface characterized by a surface dipole and a surface potential drop.

The surface double layer is important for the electrochemical potential. In Section 4.2, it was discussed that the (electro)chemical potential of the electrons depends on the potential of the metal phase. If we take the potential energy of an electron at rest outside the metal (hence E_{vac}) as a reference, the electrochemical potential can be rewritten as follows (see Eq. 56):

$$\mu_e = \mu + (-e\varphi - E_{\text{vac}}) \quad (56)$$

where μ is the contribution due to the kinetic energy of the electrons in the metal phase and $-e\varphi - E_{\text{vac}}$ is the potential energy referred to vacuum. The drop of the potential energy over the surface region is thus $-e\varphi - E_{\text{vac}}$. In Figure 15a, the situation is sketched for a metal surface where the net surface-charge density is zero. This means that the potential energy of an electron moving away from the surface reaches E_{vac} within a distance of a few unit cells from the surface plane (or jellium edge). We define the potential drop across the double layer of the metal surface as

Figure 15. Drop of the potential energy (experienced by electrons) at a metal surface. (a) The nett charge density of the metal surface is zero. The drop in the potential energy corresponds to the surface dipole layer. (b) The nett charge density of the metal surface is negative. An electron approaching the metal phase experiences the nett negative charge density over a considerable distance.

$$\Delta\phi_M = \phi - \phi_S \quad (57)$$

where ϕ_S is the electrostatic potential at the outer side of the jellium double layer (Figure 15). We can say that for an *uncharged surface* the entire difference, $-e\phi - E_{vac}$, is a good approximation of the potential drop $\Delta\phi_M = \phi - \phi_S$ across the double layer. Experimentally, $\Delta\phi_M$ can be measured with a Kelvin probe [11]. Values in the region of one eV are commonly found. This makes it clear that the electrical field in the double layer is very large.

It is of interest to discuss what happens if a metal crystal is charged. A negative charge means that the metal phase contains an excess electrons compared to the neutral state; a positive charge indicates an electron deficiency. An outcome of the jellium model is that the surface-charge density, σ , mainly affects the electron spill-over region. A net negative surface charge corresponds to a spill-over region which is somewhat more extended compared to the neutral state (Figure 13(b), dashed curve); the charge of the spill-over region is then not fully compensated by the excess posi-

tive charge at the other side of the jellium edge. The profile of the potential energy is depicted in Figure 15(b). Due to the net negative charge, an electron just outside the metal has a higher potential energy. The potential energy only reaches E_{vac} at a considerable distance from the surface. Because of the negative charge density $\delta\sigma$, the surface potential drop $\Delta\phi_M = \phi - \phi_s$ increases with respect to the neutral state. Another effect of excess electrons in the metal crystal is that the electrochemical potential, μ_e , of the electrons in the metal phase increases with respect to E_{vac} . A net negative charge makes the entire potential energy drop $-e\phi - E_{\text{vac}}$ less negative than the neutral case. In other words, the thermodynamic work function $E_{\text{vac}} - \mu_e$ decreases because of an increase in the negative surface charge.

For a further discussion of the electrochemical double layer, it is of interest to define a differential capacitance, C_M , for the jellium double layer:

$$C_M = \frac{\partial\sigma}{\partial\Delta\phi_M} = \frac{\partial\sigma}{\partial(\phi - \phi_s)} \quad (58)$$

The jellium double layer is highly polarizable and should not be compared with the classical parallel-plate capacitor. For instance, the thickness of the double layer changes with the charge density. An infinitesimal negative charge density $\delta\sigma$ (<0) on the surface leads to an extension of the spill-over region and an increase in the surface potential $\partial\Delta\phi_M = \partial(\phi - \phi_s) > 0$, hence $C_M < 0$! The double layer of the metal surface has a considerable influence on the structure of the electrochemical double layer. It will also become clear that several features of the electrochemical double layer at a metal can only be understood if the metal surface dipole is taken into account.

4.5.2 Physisorption and Chemisorption

If a gas is brought into contact with a clean metal surface, molecules will absorb on the metal surface. The metal surface itself is characterized by a dipole and a large polarizability. Dipole–dipole and London interactions act between the metal surface and the molecules; hence polar and nonpolar molecules and ions may become adsorbed. Physisorption may influence the potential energy drop $-e\phi - E_{\text{vac}}$ and, hence, the chemical potential μ_e with respect to E_{vac} . The dipole–dipole interactions can lead to a preferential orientation of physisorbed polar molecules such as H_2O .

If a metal orbital and an orbital from the absorbed species overlap considerably, bonding and antibonding orbitals are formed. The bonding and antibonding orbitals correspond to surface energy levels. The occupation of these energy levels is determined by their energy with respect to the Fermi energy μ_e . The binding energy can be considerably larger than the average thermal energy at room temperature: this corresponds to chemisorption. Consider, for instance, chemisorption of a Cl atom on a metal surface. The bonding atomic orbital lies considerably below μ_e and is occupied with two electrons. Due to the electronegativity of Cl we have a strongly polar metal–Cl bond. Chemisorption of Cl leads to a local increase of the surface dipole moment and may also increase the interfacial potential drop $\Delta\phi_M = \phi - \phi_s$.

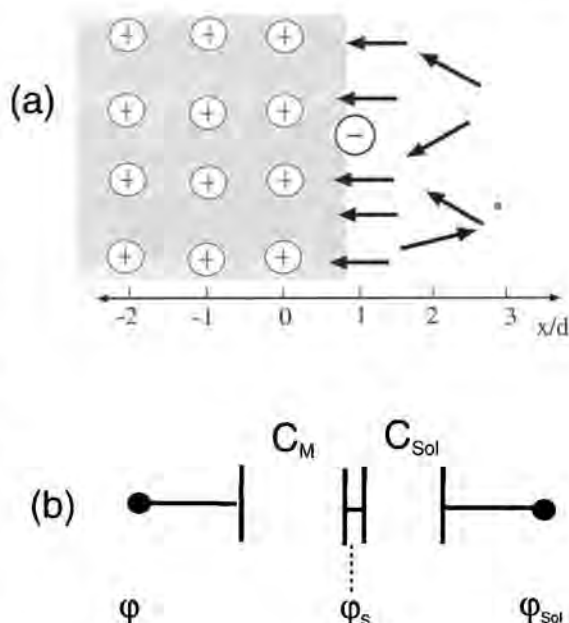

Figure 16. Schematic representation of an electrochemical double layer at a metal/electrolyte solution interface. (a) The jellium double layer (with electron spill-over region) contacts a layer of (ordered) solvent molecules, chemisorption of a negative ion is also shown. (b) Representation of the double layer capacitance as a series connection of the capacitance corresponding to the double layer of the metal surface, and the capacitance of the Helmholtz layer at the solution side.

It is clear that the interaction of molecules with the metal surface has a considerable influence on the electrochemical potential of the electrons in the metal with respect to the vacuum level.

4.5.3 The Metal/Solution Interface

Physisorption of a small number of water molecules on a clean metal surface leads to a highly oriented (sub)monolayer. If we admit more water, the molecules will interact with the first layer and hydrogen bonds will be formed. A few molecular distances away from the metal surface, the structure of the water phase becomes identical to that in the bulk. If ions are present in the water phase, they can compensate for a net charge on the metal surface. Figure 16 shows a typical structure of a metal/water electrochemical double layer. The concentration of ions in the water phase is assumed to be relatively large ($\geq 10^{-2}$ M). This means that the charge on the metal surface is compensated by ions in a narrow region, of a few Å. Figure 16(a) also shows the possibility that polarizable negative ions are chemisorbed on the metal surface.

Experimental investigations with mercury electrodes were very successful in the first half of this century [1]. Mercury has the advantage of offering a very clean surface. Moreover, with a hanging mercury drop electrode, measurement of not only the interfacial capacitance, but also the interfacial surface tension as a function of surface charge density is possible. A combination of careful experiments and subtle thermodynamic theory led to a detailed empirical picture of the mercury/

Figure 17. The double layer capacitance measured with two different metals (Ag and Hg) in an aqueous electrolyte solution as a function of the charge density at the surface. The influence of the nature of the metal phase on the total capacitance is clearest around the point of zero charge. The results are taken from W. Schmickler, *Chem. Rev.* 96, 3177 (1996).

aqueous solution interface [1]. However, the role of the metal double layer was not recognized in those days. Later measurements of the interfacial capacitance $C_{M/Sol}$ with a variety of metals and electrolyte solutions made it clear that the capacitance is determined by the nature of the metal, the solution, and the charge density. The capacitance of a Hg and a Ag electrode in aqueous solution is shown as a function of the charge density in Figure 17 [2]. It is clear that $C_{M/Sol}$ reaches a pronounced maximum near the point of zero charge ($\sigma = 0$), and that, with increasing negative and positive charge density, $C_{M/Sol}$ becomes smaller and tends to a value of about $20 \times 10^{-6} \text{ F cm}^{-2}$. The difference between the two metals is most obvious at low charge density. Measurements with different metal electrodes at the point of zero charge indicated that $C_{M/Sol}$ gradually increases with the free-electron density of the metal, and hence with the polarizability of the metal-surface double layer.

The results can be understood, at least qualitatively, if the surface double layer of the metal itself is taken into account [2]. A simple picture is presented in Figure 16; a water layer with specific orientation contacts the jellium double layer. Conceptually, the potential drop over the electrochemical double layer, $\Delta\phi_{M/Sol}$, can be separated into two contributions: a drop over the metal double layer and a drop over the first layer of solvent molecules [see Figure 16(b)]:

$$\Delta\phi_{M/Sol} = (\phi - \phi_s) + (\phi_s - \phi_{Sol}) \quad (59)$$

capacitance

Figure 18. Estimation of the capacitance of the electrochemical double layer $C_{M/Sol}$ as a function of the charge density, using a series connection of the capacitance of the double layer of the metal surface ($C_M < 0$) and the molecular Helmholtz layer (C_{Sol}). It is found that the electrochemical double layer capacitance shows a maximum at around the point of zero charge, where the influence of the metal phase is strongest. This is in qualitative agreement with the experimental results (Fig. 17). The bars on the capacitance axis indicate 2×10^{-5} F/cm², the bars on the horizontal axis indicate 5×10^{-6} C/cm².

The capacitance of the electrochemical double layer is then

$$\frac{1}{C_{M/Sol}} = \frac{\partial(\varphi - \varphi_S)}{\partial\sigma} + \frac{\partial(\varphi_S - \varphi_{Sol})}{\partial\sigma} = \frac{1}{C_M} + \frac{1}{C_{Sol}} \quad (60)$$

where the capacitance of the jellium double layer is negative (Eq. 58). For convenience we rewrite Eq. 60 as

$$C_{M/Sol} = \frac{C_M C_{Sol}}{C_M + C_{Sol}} = \frac{|C_M| C_{Sol}}{|C_M| - C_{Sol}} \quad (61)$$

It is clear that $|C_M|$ being $\frac{-\partial\sigma}{\partial(\varphi - \varphi_S)}$ should be larger than C_{Sol} if the double layer capacitance $C_{M/Sol}$ is to be positive.

Experimental results, such as those presented in Figure 17, can be interpreted on the basis of the above model (see Figure 18). It should be realized that the jellium double layer is most easily polarizable at around the point of zero charge ($\sigma = 0$); $|\partial(\varphi - \varphi_S)|$ is then largest for a given change of the charge density $\partial\sigma$. This means that $|C_M|$ is smallest around the point of zero charge (Eq. 58). To a first approximation, C_{Sol} can be assumed to be independent of the charge density. It follows then from Eq. 61 that the double-layer capacitance $C_{M/Sol}$ has a maximum at around $\sigma = 0$; and that $C_{M/Sol}$ gradually decreases to C_{Sol} with increasing positive

or negative charge density (see Figure 18). This feature agrees with the experimental results of Figure 17. The model also explains why the influence of the nature of the metal on the electrochemical double-layer capacitance is most obvious in the region of the point of zero charge. The model used here is certainly oversimplified and the agreement between the model and experimental results is only qualitative. A further discussion can be found in Ref. [2]. It is, however, clear that the highly polarizable jellium layer cannot be neglected in modern electrochemistry. Recently, strong evidence has been found to show that this layer also plays an essential role in the kinetics of electrochemical metal dissolution [14].

4.5.4 The Semiconductor/Solution Interface

Similar to metal/solution interfaces, the potential drop at the solution side of the semiconductor/electrolyte interface, $\varphi_s - \varphi_{\text{sol}}$, is determined by chemisorption of ions (such as H^+ , OH^-) and the preferential orientation of a layer of solvent molecules. However, the density of free carriers in a semiconductor is much smaller than the free-electron density in a metal. As a result, the part of the interfacial potential difference located at the solid side of the interface, that is, $\varphi - \varphi_s$, extends much deeper into the solid than for a metal/liquid interface. Investigations in the field of semiconductor electrochemistry usually deal with large-band-gap extrinsic semiconductors, that is, with $E_{\text{CB}} - E_{\text{VB}} > 1$ eV. Here, we will focus on the interface between an n -type semiconductor and a concentrated aqueous electrolyte. A similar picture is obtained for a p -type semiconductor/electrolyte interface.

An n -type semiconductor at room temperature has free electrons in the conduction band compensated by positively charged immobile ionized donors (Section 4.3.6). The concentration of free electrons (donors), n_{bulk} , is usually between 10^{16} and 10^{19} cm^{-3} , hence $10^6 - 10^3$ smaller than in a metal. A common situation is that the electrons are transferred from the semiconductor to a redox system, so that equilibrium is achieved. The surface region of the solid is then depleted of free electrons (Figure 19); a depletion layer of width d_{sc} is formed. The concentration of free electrons in the depletion layer, $n(x)$, is much smaller than the concentration of the immobile donors n_{bulk} . Thus, the charge density in the depletion layer per unit volume is en_{bulk} . Therefore, the surface charge density at the solid side is:

$$\sigma_{\text{sc}} = e \int_0^{d_{\text{sc}}} [n_{\text{bulk}} - n(x)] dx \cong en_{\text{bulk}} d_{\text{sc}} \quad (62)$$

The charge density corresponding to the depletion layer is compensated by an excess of negative ions in the solution part of the double layer (Helmholtz layer).

With en_{bulk} for the charge density per unit volume, the Poisson equation gives

$$\frac{E_{\text{CB,bulk}} - E_{\text{CB}}(x)}{-e} \cong \frac{en_{\text{bulk}}}{2\epsilon\epsilon_0} [d_{\text{sc}} - x]^2 \quad (63)$$

Figure 19. The electronic structure of an n-type semiconductor/electrolyte solution interface under conditions of free electron depletion at the surface. Shown are the conduction and valence band edges as a function of the distance from the surface. The interfacial potential drop is distributed over a region in the solid (depletion region, width d_{sc}) and the molecular Helmholtz layer at the liquid side (not shown). The interfacial capacitance is represented by a series connection of the capacitance of the depletion layer (C_{sc}) and the Helmholtz layer (C_{sol}).

and after two integrations

$$d_{sc} \cong \sqrt{\frac{2\epsilon\epsilon_0}{e^2 n_{bulk}}} \sqrt{E_{CB}(x=0) - E_{CB,bulk}} \quad (64)$$

The potential-energy difference over the depletion layer, $E_{CB}(x=0) - E_{CB,bulk}$, is often called the band bending. With $\epsilon = 10$, and $E_{CB}(x=0) - E_{CB,bulk} = 1$ eV, the width of the depletion layer is 1000, 100, and 10 nm for free carrier densities of 10^{15} , 10^{17} , and 10^{19} cm^{-3} , respectively. In Figure 19, the energy of the edges of the valence- [$E_{VB}(x)$] and conduction bands [$E_{CB}(x)$] are shown as a function of the distance from the solid surface; the electrochemical potential μ_e of the free electrons is also indicated. The concentration of free electrons at a given position in the depletion layer, $n(x)$, can be expressed as a function of the concentration in the bulk solid, n_{bulk} , with Fermi–Dirac statistics (see Section 4.3.5). From Eq. 27 it follows that

$$n(x) = n_{bulk} e^{-[E_C(x) - E_{C,bulk}]/k_B T} \quad (65)$$

The total potential drop over the interface, $\phi - \phi_{sol}$, is distributed over the depletion layer, $\phi - \phi_S = -[E_{CB,bulk} - E_{CB}(0)]/e$, and the solution side of the interface,

$\varphi_S - \varphi_{\text{Sol}}$ (see Figure 19). The capacitance of the electrochemical double layer is:

$$\frac{1}{C_{\text{Sc/Sol}}} = \frac{\partial[\varphi - \varphi_S]}{\partial\sigma} + \frac{\partial[\varphi_S - \varphi_{\text{Sol}}]}{\partial\sigma} = \frac{1}{C_{\text{Sc}}} + \frac{1}{C_{\text{Sol}}} \quad (66)$$

The entire electrochemical double layer can be represented by a series connection of two parallel plate capacitors. It is usually assumed that the structure of the double layer at the solution side does not differ much from that at a metal. The capacitance of the depletion layer is given by

$$C_{\text{SC}} = \frac{\epsilon\epsilon_0}{d_{\text{SC}}} \quad (67)$$

in which the width of the depletion layer is given by Eq. 64. Under conditions of depletion, C_{SC} is much smaller than C_{Sol} , hence $\frac{\partial[\varphi - \varphi_S]}{\partial[\varphi - \varphi_{\text{Sol}}]} \cong 1$. This means that a change in the surface charge density corresponds to a change in the width of the depletion layer solely, and that the band edges at the surface do not shift.

Surface atoms, crystal imperfections and adsorbed molecules can give rise to localized energy levels located in the band gap. These so-called surface states play an important role as mediators of interfacial electron transfer. The surface states may or may not be occupied by an electron; the surface-localized electrons give a contribution, σ_S , to the surface charge:

$$\sigma = \sigma_{\text{SC}} + \sigma_S \quad (68)$$

with

$$\sigma_S = -e \int_{E_{\text{VB}}}^{E_{\text{CB}}} s(E) f(E) dE \quad (69)$$

Here, the surface density of the states is denoted as $s(E)$ and they have an electron occupancy $f(E)$. If there is electronic equilibrium between the surface states and the free electrons in the solid, $f(E)$ is determined by the Fermi–Dirac function, Eq. 22. Under conditions of interfacial current flow, $f(E)$ may be determined by the rates of filling and emptying of the states [see Section 4.9]. If the change in the total surface-charge density corresponds to the change in the charge of the depletion layer, that is, $d\sigma_{\text{SC}} \gg d\sigma_S$, then $d(\varphi - \varphi_{\text{Sol}}) \cong d(\varphi - \varphi_S)$; only the potential drop over the depletion layer changes, the band edges at the surface do not shift when μ_e is changed. However, if $d\sigma_S$ cannot be neglected with respect to $d\sigma_{\text{SC}}$, the potential drop over the depletion layer as well as over the solvent layer changes: $d(\varphi - \varphi_{\text{Sol}}) = d(\varphi - \varphi_S) + d(\varphi_S - \varphi_{\text{Sol}})$. When μ_e is changed to a higher value with respect to a reference electrode, then $d\mu_e = dE_{\text{CB, bulk}}$. In the normal case in which $d\sigma_{\text{SC}} \gg d\sigma_S$, the band edges at the surface do not shift; $dE_{\text{CB}}(0)/d\mu_e \cong 0$. Where the surface state density (close to the Fermi level) is sufficiently high, it is possible that $0 < dE_{\text{CB}}(0)/d\mu_e < 1$.

The distribution of the interfacial potential drop over the semiconductor and the depletion layer is an important problem in the field of electrochemistry. It is often strongly related to the kinetics of interfacial electron transfer [15].

4.6 Electron Tunneling

Electron tunneling is an important mechanism for transporting electrons through solids, large molecules, and molecular complexes. Quantum-mechanical tunneling is the main mechanism of electron transfer through an interfacial layer between two condensed phases in intimate contact. From the previous section it is clear that metallic and semiconducting solids have a considerable potential-energy barrier at their surface, which confines the electrons within the solid. At or below room temperature, the classical, thermally activated escape of electrons over the surface barrier (thermionic emission) is a very improbable process, since the surface barrier is usually 50–100 $k_B T$ at room temperature. Quantum-mechanical tunneling of electrons can occur if the interfacial layer is sufficiently thin. Electron tunneling is a key feature in electrochemical electron transfer (See Sections 4.8 and 4.9). We will first discuss the probability of tunneling through a rectangular barrier between two free-electron systems [16]. We will use this result to derive the tunnel-current density between two metal phases. Finally, we will discuss experimental results dealing with tunneling between two metals separated by vacuum, an oxide layer, or water.

4.6.1 The Probability of Electron Tunneling

We consider two metallic free-electron systems, with atomically flat surfaces separated by vacuum over a distance Δx (Figure 20). In fact, the model system is an extension of the metal surface considered in Section 4.5. The complex potential energy barrier at a metal surface, discussed in Section 4.5 is simplified here to a rectangular barrier. We look for the quantum-mechanical probability that an electron in phase A is also present in phase B. This probability is given by the ratio of squared amplitudes, B^2 and A^2 , of the free-electron wave function in phase B and A, respectively. It is quantified by the transmission coefficient:

$$T[E(k_x, k_y, k_z), E_{\text{vac}}, \Delta x] = B^2/A^2 \quad (70)$$

Tunneling implies that the one-electron wave function $\psi(k_x, k_y, k_z)$ extends over the two metal phases and the vacuum in between. This wave function is a solution of the Schrödinger equations in phase A, the vacuum, and phase B. It should fulfil the following boundary conditions:

$$\begin{aligned} &\text{metal A/vacuum } (x = 0): \\ &\psi_A(x = 0) = \psi_{\text{vac}}(x = 0) \end{aligned} \quad (71)$$

Figure 20. Elastic tunneling of an electron between two metal phases separated by vacuum (rectangular barrier). Shown are the wave functions of a free electron propagating in a direction perpendicular to the interface. The wave function decays exponentially in the vacuum. The tunneling probability is related to the amplitude of the free electron wave functions (see section 6).

$$\left. \frac{\partial \psi_A}{\partial x} \right|_{x=0} = \left. \frac{\partial \psi_{vac}}{\partial x} \right|_{x=0} \quad (72)$$

and similar conditions for the boundary vacuum/metal B, ($x = \Delta x$). A wave function corresponding to an electron with a large probability for tunneling is sketched in Figure 20. The free-electron wave functions in phases A and B are given by equations such as Eq. 14. The electron wave in vacuum does not propagate, instead, the amplitude of the wave function decays exponentially; $\psi_{vac}(x) \propto e^{-\kappa_{vac}x}$ (Eq. 54),

with $\kappa_{vac} = \left[\frac{2m_e[E_{vac} - E(x)]}{\hbar^2} \right]^{1/2}$ (Eq. 55). The mathematical solution of the problem can be found in more specialized texts [16]. In practical cases, the effective barrier height is of the order of magnitude of 1 eV. The barrier width is, usually, considerably larger than the decay length of the wave function: $\kappa_{vac} \times \Delta x \gg 1$. Under these conditions (strong attenuation), the tunneling probability is found to be:

$$T = T_o e^{-2\kappa_{vac}\Delta x} \quad (73)$$

In Eq. 73, T_o is a pre-factor close to unity, which depends weakly on the effective barrier height $E_{vac} - E(x)$. The distance dependence of the tunneling probability is determined by

$$2\kappa_{vac} = 2 \times \left[\frac{2m_e[E_{vac} - E(x)]}{\hbar^2} \right]^{1/2} \quad (74)$$

This is rationalized by the fact that the probability of finding an electron in vacuum at a distance Δx from the surface of phase A is proportional to $[\psi_{vac}(\Delta x)]^2 \propto e^{-2\kappa_{vac}\Delta x}$. For an effective barrier height of 1 eV, calculation shows that $2\kappa_{vac}$ is about 1 \AA^{-1} .

The tunneling probability over a barrier of given width Δx depends critically on the effective barrier height $E_{\text{vac}} - E(x)$. We should keep in mind that the total kinetic energy of the free electrons is given by Eq. 15; $E(\vec{k}) = \frac{\hbar^2 k^2}{2m_e} = \frac{\hbar^2 (k_x^2 + k_y^2 + k_z^2)}{2m_e}$. Thus, electrons with energy close to the Fermi energy and with $k_x^2 \gg k_y^2 + k_z^2$ have the highest tunnel probability (see also Figure 4). In contrast, electrons propagating parallel to the surface plane do not tunnel.

It should be remarked here that Eq. 73 defines a dimensionless tunneling probability, not a tunneling rate or rate constant. Above, we considered a wave function extended over two metal phases; we did not consider a measurable tunneling rate. It can be expected that the lifetime of an electron in phase A before tunneling into phase B is proportional to $1/T$. In theories of electrochemical electron transfer, tunneling rate constants defined as

$$k_T = k_{T,0} \times e^{-\beta(r-r_0)} \quad (75)$$

are often used. Here, k_T is the number of tunneling events per electron level and per second; $k_{T,0}$ is the maximum number, when the electron donor and acceptor are in closest contact (at a distance r_0); $k_{T,0}$ is often related to the frequency of a nuclear vibration directly coupled to the reaction coordinate [17]; the parameter β has a meaning similar to $2\kappa_{\text{vac}}$.

4.6.2 Interfacial Electron Tunneling Between Two Metals

Above, we calculated the tunneling probability of a free electron [characterized by a wave function $\psi(k_x, k_y, k_z)$] through a barrier of a given thickness. The total interfacial current density between two metal phases separated by a barrier is the result of many discrete tunneling events with widely varying probabilities. We start with some qualitative considerations. In Figure 21(a) and (b), the situation for very low T ($T \approx 0$ K) is sketched. The occupation of the free-electron states changes abruptly from $f(E) = 1$ for $E < \mu_e$ to $f(E) = 0$ for $E > \mu_e$. In Figure 21(a), the situation for equilibrium is shown, $\mu_{e,A} = \mu_{e,B}$. Elastic tunneling between the two phases is not possible: there are no empty electron states in phase B with the same energy as the occupied states in phase A. We conclude that in the theoretical limit case of zero temperature, the exchange current at equilibrium is zero. In Figure 21(b), a non-equilibrium situation with $\mu_{e,A} > \mu_{e,B}$ is shown. Tunneling from phase A to B can occur in the entire energy region between $\mu_{e,A}$ and $\mu_{e,B}$. It is clear that tunneling from free-electron energy levels $\psi(k_x, k_y, k_z)$ with energy close to $\mu_{e,A}$ is the most likely, since the effective barrier height is then smallest. The rate of electron tunneling from A to B per range of energy is indicated by the length of arrows. Electron tunneling from B to A does not occur.

In Figure 21(c) and (d), the situation for $T \gg 0$ K (e.g., room temperature) is sketched. The occupation of states with energy around $\mu_{e,A}$ and $\mu_{e,B}$ is given by the Fermi–Dirac function, that is, $f(E, \text{phase } A) = \{1 + e^{[E - \mu_{e,A}]/k_B T}\}^{-1}$ (Eq. 22).

Figure 21. Electron tunneling between two metal phases at 0 K (a, b), and temperatures considerably above 0 K (c, d). The dashed lines show the position the electrochemical potential (Fermi-level) in a phase. The length of the arrows indicates the rate of electron transfer in an energy interval. The probability of a single tunneling event and the Fermi-Dirac occupation of the free electron energy levels is taken into account (see section 6).

The tunneling rate from phase A to B per energy interval is now determined by the transmission coefficient and the occupation factors of both phases, that is, $f(E, \text{phase A}) \times [1 - f(E, \text{phase B})]$. A similar reasoning holds for tunneling from B to A. In Figure 21(c), equilibrium is depicted. There is an energy range of a few $k_B T$ around μ_e in which $f(E, \text{phase A}) \times [1 - f(E, \text{phase B})]$ is nonzero, hence, in which tunneling from A to B can occur. The same statement holds for tunneling from B to A. Since $f(E, \text{phase A}) \times [1 - f(E, \text{phase B})]$ is a much stronger function of energy than the transmission coefficient, the tunneling rate per range of energy [arrows in Figure 21(c)] is determined by the function $f(E, \text{phase A}) \times [1 - f(E, \text{phase B})]$, peaking at the Fermi level. At equilibrium, there is a considerable electron-exchange flux, $J_{A \rightarrow B}^{\text{eq}} = J_{B \rightarrow A}^{\text{eq}} = J^{\text{eq}}$, which depends on the transmission coefficient $T[E(k_x, k_y, k_z), E_{\text{vac}}, \Delta x]$, the density of states in phases A and B, and the temperature. In Figure 21(d), a nonequilibrium situation at room temperature is shown. Tunneling from phase A to B occurs in the entire energy region between $\mu_{e,A} + k_B T$ and $\mu_{e,B} - k_B T$; the electron flux from A to B is considerably enhanced: $J_{A \rightarrow B} \gg J^{\text{eq}}$. The tunneling rate per range of energy is maximal at $\mu_{e,A}$. It is also clear that $J_{B \rightarrow A} \ll J^{\text{eq}}$. There will be a net current flow from phase A to B.

The relationship between the net electron flux $J = J_{A \rightarrow B} - J_{B \rightarrow A}$ and the difference in electrochemical potential $\mu_{e,A} - \mu_{e,B}$ will now be discussed more quantitatively.

The difference $\mu_{e,A} - \mu_{e,B}$ is often called the “bias” in physics, and the “overpotential” in electrochemistry. The rate of tunneling of an electron from phase A to B is proportional to $T[E(k_x, k_y, k_z), E_{\text{vac}}, \Delta x] \times g(E, \text{phase B}) \times [1 - f(E, \text{phase B})]$, written in compact form as $T[E] \times g(E, B) \times [1 - f(E, B)]$. Hence, the electron flux from A to B is:

$$J_{A \rightarrow B} = \Gamma \int_0^\infty T[E]g(E, A)f(E, A)g(E, B)[1 - f(E, B)] dE \quad (76)$$

Here Γ is a proportionality constant [$\text{J cm}^4 \text{ s}^{-1}$]. A similar equation holds for the electron flux from B to A. The net electron flux is hence given by

$$J[\mu_e(A) - \mu_e(B)] = \Gamma \int_0^\infty T[E]g(E, A)g(E, B)[f(E, A) - f(E, B)] dE \quad (77)$$

Close to equilibrium, where $\mu_e(A) - \mu_e(B)$ is sufficiently small, $T[E]g(E, A) \cdot g(E, B)$ is almost a constant, while $\int_0^\infty [f(E, A) - f(E, B)] dE$ is proportional to $\mu_{e,A} - \mu_{e,B}$. The net electron flux J is hence proportional to $\mu_{e,A} - \mu_{e,B}$. A region where the response of the system (here the electron flux) is proportional to a moderate deviation from equilibrium could be expected (see Section 4.2.3). For a stronger deviation from equilibrium, where $\mu_{e,A}$ is considerably above $\mu_{e,B}$, the total interfacial electron flux is dominated by tunneling from states close to $\mu_{e,A}$, where $f(E, B) \approx 0$. $T[E \cong \mu_{e,A}]$ increases strongly with $\mu_{e,A}$; from Eqs. 73–74 it follows that

$$\frac{\partial T(E \cong \mu_e)}{\partial \mu_e} = \frac{T(E \cong \mu_e) \times \kappa_{\text{vac}} \times \Delta x}{E_{\text{vac}} - \mu_e} \quad (78)$$

Hence, the net flux J increases more steeply than linear with $\mu_{e,A} - \mu_{e,B}$.

It is important to realize that the shape of the $J(\mu_{e,A} - \mu_{e,B})$ relationship is critically determined by the tunneling distance Δx . Consider, for instance, $T[E \cong \mu_{e,A}]$. From Eq. 78, it follows that:

$$\frac{\partial[\partial T(E \cong \mu_e)/\partial \mu_e]}{\partial \Delta x} = \frac{T(E \cong \mu_e) \times \kappa_{\text{vac}}}{E_{\text{vac}} - \mu_e} \times (1 - 2\kappa_{\text{vac}}\Delta x) \quad (79)$$

Since, for strong attenuation, $2\kappa_{\text{vac}}\Delta x > 1$, it holds that $\frac{\partial T(E \cong \mu_e)}{\partial \mu_e}$ decreases with increasing tunneling distance. This means that the slope of the J vs $\mu_{e,A} - \mu_{e,B}$ curve becomes less steep when the width of the barrier is increased.

4.6.3 Experimental Tunneling Spectroscopy

Before the invention of the scanning tunneling microscope (STM), planar metal/vacuum/metal and metal/insulator/metal junctions were used in studies of electron

Figure 22. The tunneling current, I , measured between two metal electrodes (tungsten en platinum) separated by a vacuum barrier as a function of the difference in electrochemical potential (here denoted as $U_{\text{emitter-anode}}$); the distance between the two electrodes (12, 20, 17 Å) is indicated in the figure. Reprinted from "Scanning Probe Microscopy and Spectroscopy", R. Wiesendanger, Cambridge University Press 1994

tunneling [16]. It is a difficult task to prepare metal/vacuum/metal junctions for quantitative studies. The metal surfaces need to be smooth on an atomic scale. The distance between the two metals should be varied between 10 to 100 Å in a controlled way. Moreover, the setup should be free from vibrations. Reliable results on vacuum tunneling between two metal electrodes were first reported in 1971 [16]. Figure 22 presents J vs $\mu_{e,A} - \mu_{e,B}$ for three separations (12, 20, and 27 Å) between the electrodes. It is clear that the tunnel current at a given bias $\mu_{e,A} - \mu_{e,B}$ is strongly dependent on the separation. The net electron flux J increases linearly with $\mu_{e,A} - \mu_{e,B}$ near equilibrium (Ohmic region), and super-linearly at higher bias, in agreement with the predictions of the previous section. It is also clear that the slope of the J vs $\mu_{e,A} - \mu_{e,B}$ relationship decreases with increasing separation, as discussed above. Much experimental work was also devoted to metal oxide-metal junctions [16]. Experimental problems were due to spatial inhomogeneities in the thickness and chemical composition of the oxide layer. The introduction of STM apparatus was accompanied by a substantial development of tunneling spectroscopy, since variation of the tip-metal distance can be more easily controlled than with planar junctions. Experimental work was often focused on the determination of the effective barrier height by measurement of the net electron flux, J , vs the separation, Δx ,

at a given bias (see Eqs. 73–74). Since tunneling from states close to $\mu_{e,B}$ forms the dominant contribution to J , the effective barrier heights, between 3 and 4 eV, were found to be close to the work function $E_{\text{vac}} - \mu_e$ of the metal under investigation.

Study of electron tunneling across an electrochemical double layer between two metals is an important subject in electrochemistry. The effective barrier height of an electrochemical double layer was obtained by variation of the substrate–tip separation. Interestingly, the barrier heights were 1–2 eV, that is, 2 eV smaller than in vacuum [2]. There have been several attempts to explain this feature. The perhaps most realistic interpretation was provided by Schmickler and coworkers [2]. They assume interaction between the tunneling electron and the electrons in the H_2O molecules. This leads to a considerable reduction of the barrier height for interaction with the H atoms, and a high barrier height when the tunneling electron interacts with oxygen. According to Schmickler, the overall effect is a reduction of the effective barrier to values in reasonable agreement with those obtained from experiments. The experimental results are important for electrochemical electron transfer between an electrode and a redox system in solution. It is found that the barrier height for electrochemical electron tunneling is 1 to 2 eV, hence considerably below the work function in vacuum. Therefore, electron tunneling across an electrochemical double layer has a higher probability than through vacuum, and the distance dependence of the tunneling rate is weaker.

4.7 Electrochemical Reactions: Kinetics and Mechanism

4.7.1 The Diversity of Electrochemical Processes

In Eqs. 80–82 some typical electrochemical equilibria are presented:

The first equation represents the equilibrium between hydrated Ag^+ ions and Ag atoms in a single-crystal configuration. Alternatively, we may say that there is a heterogeneous thermodynamic equilibrium between Ag^+ ions in the solid phase (where they are stabilized by the gas of free electrons) and Ag^+ ions in the liquid phase (stabilized by interaction with water molecules). The forward reaction step corresponds to the anodic dissolution of a silver crystal. On an atomic level, one may say that a Ag^+ core ion is transferred from the metallic phase to the liquid water phase. In an electrochemical cell, an electron flows from the Ag electrode (the working electrode) to the counter electrode each time that one Ag^+ ion is transferred from the solid to the liquid phase across the electrochemical double layer. Although the electron flow is measured in the external circuit between the working

and counter electrode, the electrochemical process itself corresponds to the transfer of an ion through the double layer. Electron transfer and tunneling are not involved.

The second equilibrium involves hydrated I^- ions in equilibrium with I_3^- complexes. In the forward step, an iodide ion donates an electron to the working electrode and is hence oxidized to a I atom. We may speculate that the I^- ion remains outside the double layer and that an electron tunnels through the double layer. However, from many experimental results and molecular dynamic simulations (see Section 4.7.2), it became clear that this is not the case. Instead, a solvated I^- ion penetrates the double layer and becomes chemisorbed as a $\text{I}^{\delta-}$ ion ($\delta < 1$) on the metal surface, losing about half of its hydration shell [18, 19]. Moreover, there is a local restructuring of the double layer. Here also, the electrochemical reaction does not involve tunneling of an electron through the double layer.

The third equilibrium involves hydrated $\text{Fe}^{2+}(\text{aq})$ and $\text{Fe}^{3+}(\text{aq})$ ions. Homogeneous electron transfer between these ions has been well studied [5]:

Here an electron is transferred from the reduced $\text{Fe}^{2+}(\text{aq})$ species to the oxidized $\text{Fe}^{3+}(\text{aq})$ species. The kinetics of this process can be followed through measurement of the concentration of $\text{Fe}^{2+}(\text{aq})$ as a function of reaction time. The fact that the homogeneous reaction in solution proceeds at a considerable rate indicates that, in the electrochemical process, the electrode acts as a sink or source of electrons only. This suggests that an electron may tunnel from an $\text{Fe}^{2+}(\text{aq})$ ion outside the double layer to an empty state in the metal, without disturbing the double layer structure. This is indeed confirmed by molecular dynamic simulations (see next section). The process shown in Eq. 82 is one of the examples where tunneling of an electron through the double layer occurs and where the reduced and oxidized species, and hence also the activated complex does not interact strongly with the electrode. This type is called an *outer-sphere electron transfer*. Since there is no breaking or formation of bonds, outer-sphere reactions are the simplest class of electrochemical reactions. For this simple class there is a sound theoretical background. Marcus was awarded with the Nobel prize in chemistry in 1992 for providing a classical model for this type of electron-transfer reaction [5]. Hopfield [20], and Levich and Doganadze have presented more elaborate quantum-mechanical models. A comprehensive review can be found in [21]. In Sections 4.8 and 4.9, we will treat simple electrochemical electron transfer similarly to electron tunneling between two metals, using the model for electron energy levels in a dissolved redox system proposed by Gerischer (see Section 4.4).

The previous discussion shows that electrochemical reactions may proceed by a variety of reaction paths. Some reactions involve transfer of ions through the double layer, in other cases an electron tunnels through the double layer without disturbing it. Many important electrochemical processes occur with bond breaking and/or bond formation; the quantitative modeling of such processes has started only recently [22]. The important reaction coordinates of electrochemical ion transfer (ECIT) reactions and electrochemical electron transfer (ECET) reactions will be discussed in the next section. In Section 4.7.3, the experimental relationship

between the rate of an electrochemical reaction and the deviation from equilibrium will be discussed. Although electrochemical processes occur by very different mechanisms, it is commonly found that the current density (hence the rate) increases exponentially with the deviation from equilibrium. This seems strange considering the large variation in mechanisms. However, a phenomenological treatment (Section 4.7.4) shows that the exponential kinetic law only implies that the energy of activation changes linearly with the deviation from equilibrium, that is, the overpotential.

4.7.2 Electrochemical Ion Transfer and Electrochemical Electron Transfer (ECIT and ECET)

Elucidation of the mechanism of an electrochemical process implies knowledge of the structure of the activated complex, and the way in which such a transition state is reached. Hence, one looks for the important reaction coordinates; these are the coordinates that critically determine the free energy of the system (molecule + electrode). Progress in this difficult field of science requires molecular dynamic simulations [18, 19], experimental data, and common sense. Here, we briefly discuss the important reaction coordinates for typical ECIT and ECET processes.

Anodic dissolution of metals (e.g., Eq. 80) has frequently been discussed in terms of electron transfer (for a review, see Ref. [14]). It is, however, clear that anodic dissolution implies the transfer of a chemical species through the electrochemical double layer. In Ref. [14], anodic dissolution was discussed as the transfer of a metal ion through the double layer, occurring in two steps. In the first step, a metal ion in the jellium plane evolves into a partially hydrated chemisorbed metal ion; this is accompanied by local restructuring of the double layer. The formation of a chemisorbed species changes the potential drop over the inner region (metal part) of the electrochemical double layer. In the second step, the partially hydrated metal ion is transferred through the outer part of the double layer, that is, the ordered layer of solvent molecules. It is shown that this model leads to a realistic relationship between anodic current density and overpotential. The model provides a microscopic interpretation of the anodic charge-transfer coefficient. The model of coupled ion transfer also explains several features of the interfacial impedance, where the classical models (based on electron transfer) failed. This work indicates that anodic dissolution can be treated more conveniently in terms of ion transfer than electron transfer.

The important reaction coordinates in ECIT and ECET processes were studied with the aid of molecular dynamic simulations together with quantum-mechanical calculations of the potential energy of the reacting system [18, 19]. This work finally leads to the free energy as a function of two important coordinates: the distance of the reacting species from the electrode surface, and the deviation of the solvation structure from equilibrium. The free-energy surface gives insight in the possible reaction pathways and transition states. As an example of an ECIT process, the oxidation of I^- to a I atom at a Pt/water interface was investigated. It was found that the distance of the ion from the electrode surface and the accompanying partial dehydration is the important reaction coordinate. The reaction proceeds via a

transition state, which strongly interacts with the metal. Finally, a chemisorbed $I^{\delta-}$ ion ($\delta < 1$) is formed.

Molecular dynamic simulations for the $Fe^{3+}(aq)/Fe^{2+}(aq)$ reaction shows that penetration of the $Fe^{2+}(aq)$ ion into the double layer leads to a huge increase of the potential energy. Penetration of a strongly hydrated $Fe^{2+}(aq)$ ion [see Section 4.4] in the double layer does not occur. Instead, an electron tunnels from an activated complex outside the double layer into an empty state of the metal. It will be shown in Section 4.8 that iso-energetic tunneling can only occur if a transition state with nonequilibrium solvation of the Fe^{2+} is formed. The formation of such a solvation structure is in many cases the rate-determining step. The time-averaged probability of nonequilibrium solvation has been considered originally by Gerischer. This “fluctuating energy level model” provides a very convenient means for treating electrochemical electron transfer similarly to interfacial electron transfer between two solids (Sections 4.8 and 4.9).

4.7.3 Current Density vs Overpotential: Experimental Results

Investigations of electrochemical kinetics are usually performed on a three-electrode electrochemical cell containing a working electrode (the electrode of interest), a counter electrode and a reference electrode. The current measured in the external circuit between working and counter electrode corresponds to the interfacial current density, j , at the working electrode multiplied with its surface area. This current density is measured as a function of the potential difference between the working and the reference electrode, $U - U_{Ref}$. In fact, the voltmeter measures the difference in electrochemical potential of the electrons in the working and reference electrodes:

$$U - U_{Ref} = -e[\mu_e - \mu_{e,Ref}] \quad (84)$$

The chemical potential of the electrons in the reference electrode does not change when the current is changed. This means that the overpotential at the working electrode can simply be controlled by $U - U_{Ref}$:

$$U - U^{eq} = (U - U_{Ref}) - (U^{eq} - U_{Ref}) = -e[\mu_e - \mu_e^{eq}] \quad (85)$$

It can be concluded that, with a conventional three-electrode electrochemical cell, the rate of the electrochemical reaction occurring at the working electrode can be measured as a function of the deviation from equilibrium.

When U is substantially more positive than U^{eq} , electrons flow from the working electrode to the counter electrode in the external circuit. This means that, at the working electrode, the anodic process prevails, that is, electrons are transferred from the reduced species to the electrode. The cathodic process occurs when $U - U^{eq}$ is negative. (By convention we take the current to be negative when a cathodic process occurs at the working electrode.) When mass transport to the working electrode does not limit the current, j changes exponentially with $U - U^{eq}$. A sketch of a typical result is shown in Figure 23. Commonly, the logarithm of the current density of the anodic and cathodic branches is plotted vs $U - U^{eq}$. In many

Figure 23. Schematic representation of the cathodic and anodic partial current densities at a metal electrode in contact with a simple redox system as a function of the overpotential $U - U^{\text{eq}}$. The bars on the vertical axis indicate one decade of current, the bars on the horizontal axis indicate 0.1 V (or 0.1 eV for the electrochemical potential scale).

cases, a linear relationship is found to hold over one to three orders of magnitude of current density. At larger overpotentials, $\ln|j|$ may increase less than linearly with $|U - U^{\text{eq}}|$. The exponential relationship between the current density and overpotential can be quantified as

$$\frac{\partial \ln[j/A \text{ cm}^{-2}]}{\partial (U - U^{\text{eq}})} = \frac{e \times \alpha_a}{k_B T} \quad \text{for } U - U^{\text{eq}} > 0 \text{ (anodic branch)} \quad (86)$$

and

$$\frac{\partial \ln[|j|/A \text{ cm}^{-2}]}{\partial (U - U^{\text{eq}})} = \frac{-e \times \alpha_c}{k_B T} \quad \text{for } U - U^{\text{eq}} < 0 \text{ (cathodic branch)} \quad (87)$$

The coefficients α_a and α_c are called the empirical charge-transfer coefficients. For simple outer-sphere electron-transfer processes, these coefficients are close to 1/2, and the current density is independent of the nature of the metal [21]. Extrapolation of the linear plots to $U - U^{\text{eq}} = 0$ gives the exchange current density at equilibrium, j^{eq} .

4.7.4 A Heuristic Treatment of Electrochemical Kinetics

Although there is strong evidence that electrochemical processes may proceed by very different pathways involving completely different reaction coordinates, it is

almost commonly observed that, around equilibrium, the current density and hence the rate of an electrochemical process increases exponentially with the overpotential (Figure 23). We may conclude that study of $j(U - U^{\text{eq}})$ is not sufficient for deriving the mechanism of an electrochemical reaction. In general, small-amplitude-modulation techniques are required together with structural information of the double layer under conditions of current flow [23]. However, it remains interesting to investigate why an exponential relationship between j and $U - U^{\text{eq}}$ is observed so commonly. This requires a heuristic and phenomenological treatment of electrochemical kinetics, without any reference to the precise mechanism [21].

We discuss a nonspecified electrochemical process denoted as

The reaction free energy, ΔG_R , is given by

$$\Delta G_R = \mu_{\text{Ox}} + \mu_e - \mu_{\text{Red}} \quad (89)$$

where μ_{Ox} and μ_{Red} are the chemical potentials of the oxidized and reduced species, respectively, and μ_e is the electrochemical potential of the electrons in the solid phase. The relationship between μ_e and the electrode potential is given by Eq. 85. Under conditions of thermodynamic equilibrium between the species in solution and the electrons in the solid phase, the reaction free energy is zero:

$$\Delta G_R \equiv 0 = \mu_{\text{Ox}}^{\text{eq}} + \mu_e^{\text{eq}} - \mu_{\text{Red}}^{\text{eq}} \quad (90)$$

The electrochemical potential of the electrons in the working electrode is then given by, $\mu_e^{\text{eq}} \equiv \mu_{\text{Red}}^{\text{eq}} - \mu_{\text{Ox}}^{\text{eq}}$, this corresponds to the electrode potential U^{eq} .

The net rate of the electrochemical process at the working electrode is directly related to the net current density j given by

$$j = j_a + j_c = j_a - |j_c| = e[k_a c_{\text{red}} - k_c c_{\text{Ox}}] \quad (91)$$

In Eq. 91, the concentrations of the oxidized and reduced species just outside the electrochemical double layer are used (number of molecules per cm^3); k_a and k_c are the electrochemical rate constants (cm s^{-1}) for the anodic and cathodic process, respectively. As for chemical processes, it is assumed that the forward and backward reactions proceed via an activated complex (transition state), see Figure 24. The rate constants can then be written as:

$$k_a = A_a e^{-\Delta G_a^* / k_B T} \quad (92)$$

$$k_c = A_c e^{-\Delta G_c^* / k_B T} \quad (93)$$

Since a deviation of the electrode potential from equilibrium changes the rates of the anodic and cathodic process, the activation energies must be a function of

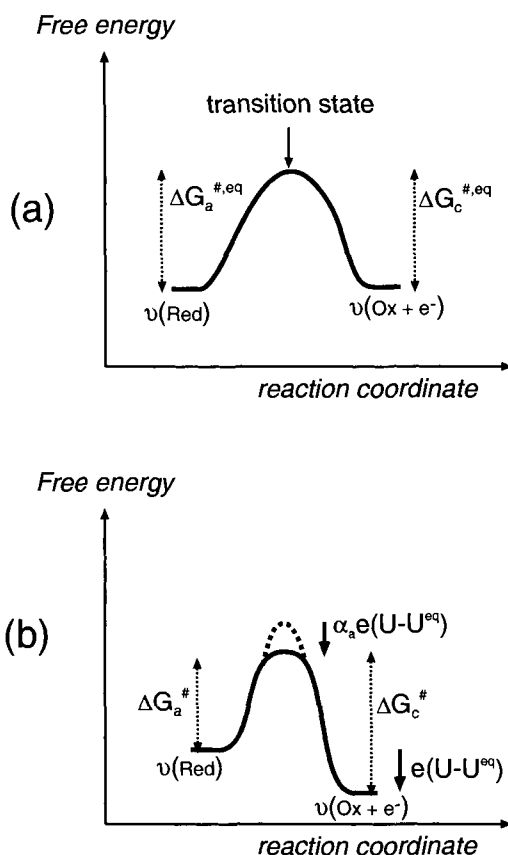

Figure 24. Free energy diagrams corresponding to the heuristic model for electrochemical reactions presented in section 7.4. The upper diagram represents the situation at electrochemical equilibrium; the lower diagram represents the situation where $U > U^{\text{eq}}$ (nett anodic current flow).

$U - U^{\text{eq}}$. We therefore write the activation energies as Taylor expansions around U^{eq} :

$$\begin{aligned} \Delta G_a^\ddagger(U - U^{\text{eq}}) &= \Delta G_a^{\ddagger, \text{eq}} + \left. \frac{\partial \Delta G_a^\ddagger}{\partial (U - U^{\text{eq}})} \right|_{\text{eq}} \times (U - U^{\text{eq}}) \\ &\quad + \frac{1}{2} \left. \frac{\partial^2 \Delta G_a^\ddagger}{\partial (U - U^{\text{eq}})^2} \right|_{\text{eq}} \times (U - U^{\text{eq}})^2 + \dots \end{aligned} \quad (94)$$

$$\begin{aligned} \Delta G_c^\ddagger(U - U^{\text{eq}}) &= \Delta G_c^{\ddagger, \text{eq}} + \left. \frac{\partial \Delta G_c^\ddagger}{\partial (U - U^{\text{eq}})} \right|_{\text{eq}} \times (U - U^{\text{eq}}) \\ &\quad + \frac{1}{2} \left. \frac{\partial^2 \Delta G_c^\ddagger}{\partial (U - U^{\text{eq}})^2} \right|_{\text{eq}} \times (U - U^{\text{eq}})^2 + \dots \end{aligned} \quad (95)$$

If the first-order partial derivatives are (nearly) independent of the overpotential

$U - U^{\text{eq}}$, we may neglect the second- and higher-order terms in the expansion. In this case we define

$$\alpha_a = \frac{-1}{e} \left. \frac{\partial \Delta G_a^\ddagger}{\partial (U - U^{\text{eq}})} \right|_{\text{eq}} \quad (96)$$

$$\alpha_c = \frac{1}{e} \left. \frac{\partial \Delta G_c^\ddagger}{\partial (U - U^{\text{eq}})} \right|_{\text{eq}} \quad (97)$$

The first-order derivatives correspond to the *charge-transfer coefficients* for the anodic and cathodic processes, respectively.

It generally holds that (see also Figure 24)

$$\Delta G_a^\ddagger - \Delta G_c^\ddagger = \mu_{\text{Ox}} + \mu_e - \mu_{\text{Red}} \quad (98)$$

and hence at equilibrium that

$$\Delta G_a^{\ddagger, \text{eq}} = \Delta G_c^{\ddagger, \text{eq}} \equiv \Delta G^{\ddagger, \text{eq}} \quad (99)$$

When the second- and higher-order terms in the Taylor's expansion of the activation energies can be neglected, we have:

$$\Delta G_a^\ddagger (U - U^{\text{eq}}) = \Delta G^{\ddagger, \text{eq}} - \alpha_a \times e(U - U^{\text{eq}}) \quad (100)$$

and

$$\Delta G_c^\ddagger (U - U^{\text{eq}}) = \Delta G^{\ddagger, \text{eq}} + \alpha_c \times e(U - U^{\text{eq}}) \quad (101)$$

From Eqs. 92–93 and 100–101, it follows that we can write the rate constants as follows

$$k_a = k_a^{\text{eq}} e^{\alpha_a \times e(U - U^{\text{eq}})/k_B T} \quad (102)$$

$$k_c = k_c^{\text{eq}} e^{-\alpha_c \times e(U - U^{\text{eq}})/k_B T} \quad (103)$$

Substitution of the rate constants in Eq. 91 gives the total current density:

$$j = j^{\text{eq}} [e^{\alpha_a \times e(U - U^{\text{eq}})/k_B T} - e^{-\alpha_c \times e(U - U^{\text{eq}})/k_B T}] \quad (104)$$

The exchange current density at equilibrium is given by

$$j^{\text{eq}} = ek_a^{\text{eq}} c_{\text{red}} = ek_c^{\text{eq}} c_{\text{ox}} \quad (105)$$

Equation 104 is known as the Butler–Volmer equation. In many cases, it agrees with the experimental $j(U - U^{\text{eq}})$ relationship, see previous section. The above treatment shows that an exponential $j(U - U^{\text{eq}})$ relationship can be explained

simply if it is assumed that the activation energy changes linearly with the overpotential. The fact that deviations from this exponential relationship occur at higher overpotentials indicate that the second-order terms in the Taylor's expansions (Eqs. 94–95) cannot be neglected. It is the task of microscopic theories to explain why the activation energy changes linearly with the overpotential in a limited region around equilibrium. For ECIT it has recently been found that the activation energy depends on the charge density on the electrode, and may vary linearly with the overpotential [19]. For outer-sphere electron transfer, there are well-established microscopic theories that explain a linear relationship between overpotential and activation energy [5, 12, 15, 21], see Sections 4.8 and 4.9.

Experimentally, it is often found that the anodic and cathodic charge transfer coefficients are about 1/2. This is typically the case for outer-sphere electron transfer. Values between zero and one are found for several more complex reactions. We now consider whether this behavior is reasonable in the framework of the phenomenological model presented here. In an outer-sphere process, the oxidized and reduced species are outside the electrochemical double layer. The chemical potential of these species is then not influenced by the electrode potential, and the following is valid:

$$\text{and } \left. \begin{array}{l} \mu_{\text{Ox}} = \mu_{\text{Ox}}^{\text{eq}} \\ \mu_{\text{Red}} = \mu_{\text{Red}}^{\text{eq}} \end{array} \right\} \quad (106)$$

Also, in the case of more complex electrochemical processes, these conditions may hold. Consider, for instance, the electrochemical equilibrium between Ag and Ag^+ (aq) (Eq. 80). The hydrated silver ion is, finally, outside the double layer; its chemical potential does not depend on the electrode potential. Since a change of the electrode potential only affects the interfacial potential drop and μ_e (see Section 4.5), it is reasonable to assume that the chemical potential of the silver atoms in the silver phase is also independent of the electrode potential. Hence, also in the case of Eq. 80, the polarization $U - U^{\text{eq}}$ leads to a change of μ_e only. In contrast, if products or reactants are chemisorbed on the electrode, their chemical potential depends on the electrode potential. If the conditions presented by Eqs. 106 are valid, it also holds that

$$\Delta G_a^\ddagger - \Delta G_c^\ddagger = \mu_e - \mu_e^{\text{eq}} = -e(U - U^{\text{eq}}) \quad (107)$$

and, since in the linear case $\Delta G_a^\ddagger = \Delta G^{\ddagger, \text{eq}} - e\alpha_a(U - U^{\text{eq}})$ and $\Delta G_c^\ddagger = \Delta G^{\ddagger, \text{eq}} + e\alpha_c(U - U^{\text{eq}})$, Eq. 107 implies that $\alpha_a + \alpha_c = 1$. In the case of an outer-sphere electron-transfer process, the transition state remains outside the double layer. Transfer coefficients of 1/2 are then made reasonable by the assumption that the electron occupation of the transition state is 1/2. The energy of the transition state then contains a contribution of 1/2 μ_e . This agrees with transition states proposed for homogeneous outer-sphere reactions [5].

4.8 Electron Transfer between a Metal and a Simple Redox System

In Section 4.8.2, we will calculate the net flow of electrons between a metal electrode and a simple redox system as a function of the difference of the electrochemical potentials in both phases. We will, therefore, consider all possible elastic tunneling events between discrete electron energy levels on both sides of the interface. The energetic distribution of electron energy levels in the metal has been discussed in Section 4.3. The distribution of electron energy levels corresponding to the redox system in solution is provided by the fluctuating-energy-level model proposed by Gerischer [12] (Section 4.4). The procedure which will be followed is similar to that used in the calculation of the net electron flux between two metals. In Section 4.8.3, we will compare the results with those obtained from an independent theory, developed by Marcus [5]. We will also consider the results of both microscopic theories with regard to the phenomenological framework developed in Section 4.7. First, some remarks on the analogy between electrochemical electron tunneling and tunneling between two metals are made in Section 4.8.1.

4.8.1 Comparison between Electrochemical Electron Tunneling and Tunneling between Two Metals

In Section 4.6.1, we discussed the probability of an elastic tunneling event between two electron-energy levels corresponding to free electrons (Eqs. 73–75). In electrochemical electron tunneling, we consider tunneling between free-electron levels in the metal and electronic orbitals localized on the oxidized or reduced species. When these orbitals interact weakly with the free-electron levels, expressions similar to Eqs. 73–74 are valid for the tunneling probability. In fact, in the literature, one often finds an expression similar to Eq. 75 to describe the distance dependence of the rate of electron tunneling between molecular levels [17, 21]. In the following section, it is implied that in the electrochemical case, the probability of elastic tunneling is described by equations analogous to those derived for vacuum tunneling between free-electron levels. There is experimental evidence that shows that tunneling between two metals through an electrochemical double layer is characterized by a considerably lower effective barrier height than vacuum tunneling (see Section 4.6.3). For tunneling through an electrochemical double layer, the effective barrier height is 1–2 eV [2]. Thus, the attenuation of the probability of electron tunneling with distance is less than in vacuum.

Redox ions in solution are subject to chaotic Brownian movement. In principle, a certain range of tunneling distances between the metal and the redox species should be taken into account in a kinetic theory. The tunneling probability decays exponentially with increasing distance between the metal and the redox ion. Only redox ions nearest to the metal surface are, therefore, taken into account. Then, the inner solvation shell of the ion contacts the Helmholtz layer. There is no penetration of the reacting system into the electrochemical double layer (See Section 4.7.2).

4.8.2 Current Density as a Function of Overpotential

We consider an outer-sphere electrochemical reaction between a metal and a simple redox system, once again using the reaction depicted in Eq. 35:

The electrochemical potential of a free electron system in equilibrium with the redox system is:

$$\mu_e(\text{Ox/Red}) = \mu^o(\text{Ox/Red}) + k_B T \ln(c_{\text{Red}}/c_{\text{Ox}}) \quad (108)$$

The electrochemical potential of the working electrode, μ_e , can be controlled with respect to a reference potential by use of a three-electrode electrochemical cell. One can then measure the rate of electrochemical electron transfer (by the current density j in the external circuit) as a function of the deviation from equilibrium, $\mu_e - \mu_e^{\text{eq}}$.

The energetic distribution of the electron energy levels on both sides of the electrochemical double layer is depicted in Figure 25. In Figure 25(a), the situation for electrochemical equilibrium is given, $\mu_e^{\text{eq}} = \mu(\text{Ox/Red})$; in Figure 25(b), μ_e is higher than μ_e^{eq} , thus, a net flow of electrons from the metal to the oxidized species occurs (net cathodic current flow). The energetic distribution of the electron levels corresponding to the redox system has been discussed in Section 4.4. The time-averaged

Figure 25a. Electron exchange between a metal and a simple redox system in solution under conditions of electrochemical equilibrium, $\mu_e = \mu(\text{Ox/Red})$. The energy distribution of the occupied and empty electron levels in the metal and in the redox system are depicted. Elastic tunneling occurs between occupied and empty levels on both sides of the interface. The rate of exchange is maximal at around the Fermi-level as indicated by the length of the arrows.

Figure 25b. Cathodic electron transfer between a metal and a simple redox system in solution for a moderate deviation from equilibrium, $\mu_e > \mu(\text{Ox/Red})$. The energy distribution of the occupied and empty electron levels in the metal and in the redox system are depicted. Elastic tunneling occurs between occupied and empty levels on both sides of the interface. The rate of exchange is maximal at around the Fermi-level in the metal (see length of arrows).

Figure 25c. Cathodic electron transfer between a metal and a simple redox system in solution under strong deviation from equilibrium, $\mu_e \geq \mu(\text{Ox/Red}) + \lambda$. The dominant contribution to the cathodic current is provided by tunneling in the energy interval at around the energy of the most probable empty state corresponding to the oxidized species (see length of arrows).

probability that an oxidized species corresponds to an empty energy level of energy E is given by $W_{\text{Ox}}(E)$; the probability of finding an occupied energy level at an energy E is given by $W_{\text{Red}}(E)$, with

$$W_{\text{Ox}}(E) = (4\pi k_B T \lambda)^{-1/2} e^{-(E - E_{\text{Ox}}^{\text{eq}})^2 / 4\lambda k_B T} \quad (47)$$

$$W_{\text{Red}}(E) = (4\pi k_B T \lambda)^{-1/2} e^{-(E - E_{\text{Red}}^{\text{eq}})^2 / 4\lambda k_B T} \quad (48)$$

In Figure 25, we took a typical value of 1 eV per molecule for the reorganization energy λ .

The net current flow through the external circuit between the working and counter electrode is given by

$$j = j_a + j_c = e(k_a c_{\text{Red}} - k_c c_{\text{Ox}}) \quad (109)$$

Here, k_a and k_c are the electrochemical rate constants (cm s^{-1}) and c_{Red} and c_{Ox} are the concentrations of the redox ions just outside the electrochemical double layer. The anodic current is due to electron transfer from the reduced species to the empty states in the working electrode, the cathodic current is due to transfer from an occupied electron level in the metal to an unoccupied level corresponding to the oxidized species. We evaluate the electrochemical rate constants by taking into account all elastic tunneling events between the energy levels in the metal, $g(E)$, and those in the electrolyte, given by $W_{\text{Ox}}(E)c_{\text{Ox}}$ and $W_{\text{Red}}(E)c_{\text{Red}}$. The procedure is similar to that described in Section 4.6.2. Thus:

$$k_a = \Gamma \int_{-\infty}^{E_{\text{vac}}} T(E) W_{\text{Red}}(E) g(E) [1 - f(E)] dE \quad (110)$$

and

$$k_c = \Gamma \int_{-\infty}^{E_{\text{vac}}} T(E) W_{\text{Ox}}(E) g(E) f(E) dE \quad (111)$$

A close inspection of Figures 25(a) and (b) shows that, under conditions of equilibrium or sufficiently small overpotential ($|\mu_e - \mu_e^{\text{eq}}| < \lambda$), electron tunneling occurs predominantly in the energy range around the Fermi level of the metal. This is because the occupancy of the electron levels in the metal and redox system are given by the Fermi–Dirac law. To a good approximation, we may confine the integration to the energy range between $\mu_e - k_B T$ and $\mu_e + k_B T$; thus

$$k_a = k_B T \times \Gamma \times T(\mu_e) \times g(\mu_e) \times W_{\text{Red}}(\mu_e) \quad (112)$$

and

$$k_c = k_B T \times \Gamma \times T(\mu_e) \times g(\mu_e) \times W_{\text{Ox}}(\mu_e) \quad (113)$$

In the equations for the probability functions $W_{\text{Red}}(\mu_e)$ and $W_{\text{Ox}}(\mu_e)$, we can use

$$\begin{aligned}\mu_e - E_{\text{Red}}^{\text{eq}} &= [\mu_e - \mu^o(\text{Ox/Red})] + \lambda = [\mu_e - \mu(\text{Ox/Red})] \\ &\quad + [\mu(\text{Ox/Red}) - \mu^o(\text{Ox/Red})] + \lambda\end{aligned}$$

and

$$\begin{aligned}\mu_e - E_{\text{Ox}}^{\text{eq}} &= [\mu_e - \mu^o(\text{Ox/Red})] - \lambda \\ &= [\mu_e - \mu(\text{Ox/Red})] + [\mu(\text{Ox/Red}) - \mu^o(\text{Ox/Red})] - \lambda\end{aligned}$$

(see Figure 12 and Eq. 46). Furthermore, $\mu_e - \mu(\text{Ox/Red})$ is $\mu_e - \mu_e^{\text{eq}}$, and the difference $\mu(\text{Ox/Red}) - \mu^o(\text{Ox/Red})$ is given by Eq. 36. Since we assumed a small overpotential, that is, $\mu_e - \mu^o(\text{Ox/Red}) < \lambda$, the exponent in the equations for $W_{\text{Red}}(\mu_e)$ and $W_{\text{Ox}}(\mu_e)$ can be simplified. It is found that

$$k_a = k_a^{\text{eq}} e^{-(\mu_e - \mu_e^{\text{eq}})/2k_B T} \quad (114)$$

with

$$k_a^{\text{eq}} = \frac{k_B T \times \Gamma \times T(\mu_e) \times g(\mu_e)}{\sqrt{4\pi k_B T \lambda}} \times \sqrt{\frac{c_{\text{Ox}}}{c_{\text{Red}}}} \times e^{-\lambda/4k_B T} \quad (115)$$

and

$$k_c = k_c^{\text{eq}} e^{(\mu_e - \mu_e^{\text{eq}})/2k_B T} \quad (116)$$

with

$$k_c^{\text{eq}} = \frac{k_B T \times \Gamma \times T(\mu_e) \times g(\mu_e)}{\sqrt{4\pi k_B T \lambda}} \times \sqrt{\frac{c_{\text{Red}}}{c_{\text{Ox}}}} \times e^{-\lambda/4k_B T} \quad (117)$$

Equations 115 and 117 satisfy the necessary condition $k_a^{\text{eq}} c_{\text{Red}} = k_c^{\text{eq}} c_{\text{Ox}}$ at electrochemical equilibrium. The activation energy is $\lambda/4$ for exchange at equilibrium. The anodic and cathodic partial current densities change exponentially with the deviation from equilibrium, $\mu_e - \mu_e^{\text{eq}}$. This holds as long as the concentrations of the reduced and oxidized species just outside the double layer are independent of the overpotential (kinetic control), and the overpotential is sufficiently small with respect to the reorganization energy, that is, $|\mu_e - \mu_e^{\text{eq}}| < \lambda$. It is clear that the current density shows a sub-exponential increase at larger overpotentials. Consider, for example, the case of cathodic electron flow, with μ_e close to the maximum of the probability function of the oxidized species, $\mu_e \approx E_{\text{Ox}}^{\text{eq}}$ [Figure 25(c)]. When we increase the overpotential further, electron tunneling in the energy range around $E_{\text{Ox}}^{\text{eq}}$ remains the dominant contribution to the cathodic current; hence, the overall cathodic current flow will tend to a constant value.

4.8.3 Marcus, Gerischer and the Phenomenological Rate Equations

In the years 1955–1960, a kinetic theory for homogeneous outer-sphere electron transfer was put forth by Marcus [5]. Marcus pointed out that simple electron transfer reactions, as described by Eqs. 30–31, cannot occur if the reaction complex has an equilibrium solvation structure. This would imply that the reacting system consisting of two ions exchanging an electron has the wrong solvation sphere after the transfer of the electron. In such a way, tunneling cannot proceed iso-energetically. Marcus proposed that, for the Franck–Condon principle to be obeyed during elastic tunneling, tunneling occurs in an activated complex characterized by a non-equilibrium solvation structure. This activated complex should have a free energy which is independent of the position of the electron in transition. With the use of classic electrostatic theory, Marcus was able to find the activated complex with the lowest free energy, and hence to predict the most probable reaction path for simple electron transfer. At a later stage, the theory was adapted for the case of electrochemical electron transfer between a metal and a simple redox system. The activation energy for anodic and cathodic electron transfer can be written as follows:

$$\Delta G_a^\# = \frac{\lambda}{4} \left(1 + \frac{\mu_e - \mu_e^{\text{eq}}}{\lambda} \right)^2 \quad (118)$$

$$\Delta G_c^\# = \frac{\lambda}{4} \left(1 - \frac{\mu_e - \mu_e^{\text{eq}}}{\lambda} \right)^2 \quad (119)$$

Here, λ is the reorganization energy composed of a component due to vibrational excitations in the ligand–metal ion bonds and a component due to the non-equilibrium solvation sphere. Using classic electrostatic theory, Marcus was able to find an expression for the reorganization energy of the solvation structure as a function of the radii of the reduced and oxidized species and the static dielectric constant of the solvent. In the decades after the appearance of the first papers, it became clear that the predictions of Marcus are in qualitative, and sometimes quantitative agreement with the results of many experiments in the field of homogeneous, intramolecular and electrochemical electron transfer. In the following, we place the predictions of the microscopic classical theories of Marcus and Gerischer in the framework of the general and phenomenological treatment presented in Section 4.7.

At equilibrium, that is, $\mu_e = \mu_e^{\text{eq}}$, the Marcus theory predicts that the activation energy for electron exchange between the metal and redox system is $\lambda/4$ (see Eqs. 118–119). This is the same as the prediction of the Gerischer theory, Eqs. 115 and 117. Moreover, it appeared that the reorganization energy λ has the same meaning in both theories. In Section 4.4, a definition for λ within the Gerischer model was given by Eq. 46. Marcus found a quantitative expression for this quantity. Experimentally, the activation energy $\lambda/4$ can be obtained from the temperature dependence of the exchange current at equilibrium (see Section 4.7.3). Values on the order of 0.1 to 0.5 eV are usually found, in qualitative agreement with the prediction from

the Marcus theory that for most redox systems λ should lie in the range 0.5–2 eV per molecule [5].

We now consider the results for a sufficiently low overpotential, that is, $|\mu_e - \mu_e^{\text{eq}}| < \lambda$. For example, we take $\mu_e > \mu_e^{\text{eq}}$ (net cathodic current flow). The Marcus theory predicts that $\Delta G_a^\# = \frac{\lambda}{4} + \frac{1}{2}(\mu_e - \mu_e^{\text{eq}})$, and $\Delta G_c^\# = \frac{\lambda}{4} - \frac{1}{2}(\mu_e - \mu_e^{\text{eq}})$ (see Eqs. 118–119). This is in complete agreement with the predictions of the Gerischer theory, described by Eqs. 114–119. This means that in the framework of the phenomenological theory (Section 4.7, Eqs. 100–101) the charge-transfer coefficients are independent of the overpotential and temperature, that is, $\alpha_a = \alpha_c = 1/2$. Charge-transfer coefficients close to 1/2 have been found for many simple redox systems [21].

At higher overpotential, $\mu_e - \mu_e^{\text{eq}}$ can become close to, or even higher than λ . If the graphical description of the Gerischer theory is used (Figure 25), it follows that cathodic electron transfer will predominantly occur by tunneling in the energy range close to $E_{\text{Ox}}^{\text{eq}}$. It follows that the rate of cathodic transfer will increase less than exponentially with $\mu_e - \mu_e^{\text{eq}}$. If μ_e becomes equal to or higher than $E_{\text{Ox}}^{\text{eq}}$, the cathodic current will tend to a constant maximum value. The Marcus theory also predicts that the current increases less than exponentially with the overpotential if the condition $|\mu_e - \mu_e^{\text{eq}}| < \lambda$ is not fulfilled. Furthermore, it predicts that the current *decreases* with increasing overpotential if $\mu_e - \mu_e^{\text{eq}}$ becomes greater than λ . Experimental evidence for this so-called inverted region has been put forward for homogeneous and intramolecular electron transfer. It is clear from Figure 25 that an inverted regime cannot occur for electrochemical electron transfer at a metal electrode. Electron tunneling in the energy range around $E_{\text{Ox}}^{\text{eq}}$ remains the dominant contribution to the cathodic current if $\mu_e - \mu_e^{\text{eq}}$ is made higher than λ .

4.9 Comparison of Electron Transfer at a Semiconductor With Electron Transfer at a Metal Electrode

With the development of solid-state semiconductor devices (diodes, transistors), semiconductor/solution interfaces [24] became a subject of scientific interest. Since the 1960s, semiconductor electrochemistry and photo-electrochemistry has become established as an independent subdiscipline in electrochemical science. The basic principles and summaries of experimental results can be found in review papers and textbooks [25]. Here, we will introduce the subject by comparing simple electron transfer at a metal with that at a semiconductor electrode.

The main differences between the kinetics of electron transfer at a metal and that at a semiconductor electrode originate in the difference in the density of free carriers. In a typical metal, the electrochemical potential or Fermi level, μ_e , is located in a band. The free-electron density is huge, 10^{22} – 10^{23} cm⁻³. We discussed the metal/solution interface in Section 4.5; it has a rather complicated structure with a double

Figure 26. Electronic structure of an interface between an *n*-type semiconductor and an electrolyte solution containing a simple redox system. The conduction band edge is shown as a function of the distance from the surface at the left side (solid line: equilibrium, dashed line: nett cathodic current flow). At the other side, the energetic distribution of empty and occupied electron levels corresponding to the redox system is shown. Electron transfer is possible in the energy region just above the conduction band edge at the surface.

layer at the metal surface extending over a few unit cells adjacent to a molecular solvent layer. However, the width of the entire double layer is less than a nanometer. This means that free electrons in the bulk are in tunneling distance from redox ions contacting the solution part of the double layer. Moreover, the density of occupied and empty free electron states with energy close to μ_e is large. Typically, electrochemical electron tunneling occurs in the energy range between $\mu_e - k_B T$ and $\mu_e + k_B T$ (see Section 4.8). At equilibrium, isoenergetic electron tunneling may occur if the reduced or oxidized species has an electron level in this energy range. This requires a nonequilibrium solvation structure around the reacting ion, corresponding to a thermal activation energy given by one fourth of the reorganization energy of the redox system.

In bulk semiconductors, the electrochemical potential is in the gap between the valence and conduction bands (see Section 4.3.5). The density of free carriers (holes in the VB and free electrons in the CB) is 10^{16} – 10^{19} cm^{-3} , this is three to six orders of magnitude smaller than in a metal. The consequences for the structure of the semiconductor/solution interface were discussed in Section 4.5.4. In Figure 26, the interface between an *n*-type semiconductor and an electrolyte is depicted; the energetic distribution of electron levels corresponding to the redox system is also shown (see also Sections 4.4 and 4.8; for simplicity we assumed here that $c_{Ox} = c_{Red}$). In Figure 26, the situation at equilibrium is shown. The interfacial region consists of a layer in the solid, depleted of free electrons (typically 10–1000 nm in thickness), adjacent to the Helmholtz layer at the solution side. Electrons in the bulk of the semiconductor are therefore much too far from the redox ions for tunneling to be possible. Cathodic tunneling from the semiconductor to an oxidized species only involves electrons at the surface, with potential energy equal to $E_{CB}(0)$. It follows that, in such a situation, the activation energy is considerably larger than $\lambda/4$, since

an electron from the bulk has to overcome the potential-energy barrier of the depletion layer. This also becomes apparent if anodic transfer from a reduced species to the empty states in the conduction bands is considered. Tunneling is possible in the energy range above $E_{CB}(0)$ only. The probability of finding a filled level corresponding to the reduced species in this energy range is very low. Again, we conclude that the activation energy is much higher than for electron exchange between a redox system and a metal. The activation energy for electron exchange between an *n*-type semiconductor electrode and a redox system has been calculated on the basis of the fluctuating-energy-level model [15]. It is found that

$$\Delta G^{\#,\text{eq}} = \lambda/4 + \frac{E_{CB}(0) - \mu(\text{Ox/Red})}{2} + \frac{[E_{CB}(0) - \mu(\text{Ox/Red})]^2}{4\lambda} \quad (120)$$

The activation energy exceeds $\lambda/4$; the additional contributions depend on the degree of depletion at equilibrium and they can easily be as large as $\lambda/4$ itself. Hence, the exchange current density between a typical *n*-type semiconductor and a simple redox system can be orders of magnitude lower than that in a metal.

The high activation energy for direct exchange between a semiconductor and a redox system opens the gate for competitive pathways, that is, for exchange mediated by surface-electron levels located in the band gap (surface states). In Figure 27, electron exchange between an *n*-type semiconductor and a simple redox system, mediated by surface states, is shown. The exchange between surface states located at around μ_e and a simple redox system across the Helmholtz layer requires an activation energy of $\lambda/4$. The exchange of electrons between surface levels and the free electron levels (conduction band) in the bulk semiconductor requires a thermal activation energy of the order of $E_{CB}(0) - \mu(\text{Ox/Red})$. Thus, electron exchange mediated by surface energy levels is a two-step process; both steps can proceed

Figure 27. Representation of the competition between direct electron exchange (at around the conduction band edge at the surface) and exchange mediated by surface electron levels. Surface states may exchange electrons with the redox system in the energy interval at around the electrochemical potential. Surface states exchange electrons with the conduction band by electron capture and thermal electron excitation (vertical arrows).

Figure 28. Diagram showing the competition between direct and surface state mediated electron exchange between an *n*-type semiconductor and a simple redox system ($\lambda = 1$ eV). The competition is determined by the effective density of surface states at around the Fermi-level [$2 k_B T s$] and the band bending at equilibrium [$E_{CB}(0) - \mu(\text{Ox/Red})$]. The demarcation line indicates equal rate of both processes.

with considerably lower activation energy than that for direct exchange given by Eq. 120. It is clear that the competition between direct and surface-state-mediated exchange depends on the reorganization energy λ of the redox system, the degree of depletion at equilibrium, that is, $E_{CB}(0) - \mu(\text{Ox/Red})$, and the density of surface energy levels as a function of energy in the band gap. A general analysis of the competition between direct and surface-state-mediated exchange is out of reach. In [15], the problem was simplified by it being pointed out that surface states at around μ_e are the most effective in electron exchange between a semiconductor and a simple redox system under equilibrium conditions. (This is not necessarily the case under net cathodic or anodic current flow). The effective density of these states is denoted as $k_B T \times s(\mu_e)$ (cm^{-2}). The competition between surface-state-mediated and direct exchange is represented in Figure 28 by the demarcation line in the diagram, with $\log_{10}[k_B T \times s(\mu_e)]$ and $E_{CB}(0) - \mu(\text{Ox/Red})$ as coordinate axes. If the depletion at equilibrium is relatively weak, say 0.1 eV, the effective density must be higher than 10^{12} cm^{-2} to make surface-state-mediated transfer competitive with direct transfer. But, for a moderate band bending of 0.3 eV, a density of surface states of 10^9 cm^{-2} suffices. Reducing the density of surface states at a semiconductor/solution interface below a value of 10^9 cm^{-2} is a difficult task. It is probably only possible with layered semiconductors and hydrogen-terminated silicon surfaces [26]. This may explain why, in so many cases, experimental results indicate that surface states are involved to a large extent in electron exchange at equilibrium and in a net cathodic or anodic current flow [15, 25].

When we make the electrochemical potential, μ_e , of a metal or semiconductor electrode different from the value at equilibrium, $\mu_e^{\text{eq}} = \mu(\text{Ox/Red})$, the interfacial potential drop $\varphi - \varphi_{\text{Sol}}$ is changed, and $\partial(\mu_e - \mu_e^{\text{eq}}) = -e\partial(\varphi - \varphi_{\text{Sol}})$. With a metal electrode, the only effect for the electrochemical kinetics is that μ_e is changed with respect to the distribution of electron levels corresponding to the redox system. As a

result, the probability of electron transfer from the metal to the oxidized species, and from the reduced species to the metal is changed (see Section 4.8.2). With a semiconductor electrode under conditions of depletion, a change of the overpotential $\partial(\mu_e - \mu_e^{\text{eq}})$ can result in a change of the potential drop over the depletion and Helmholtz layers; $\partial(\mu_e - \mu_e^{\text{eq}}) = -e[\partial(\varphi - \varphi_S) + \partial(\varphi_S - \varphi_{\text{Sol}})]$. Where the occupation of surface energy levels is not changed with the overpotential, the distribution of $\partial(\mu_e - \mu_e^{\text{eq}})$ over the interfacial layers is determined by the relative value of the capacity of the depletion and Helmholtz layers, that is, by the parameter

$\frac{C_{\text{sol}}}{C_{\text{Sc}} + C_{\text{Sol}}}$ (Section 4.5.4). If the density of free carriers is not too high (below

10^{18} cm^{-3}), it usually holds that $\frac{C_{\text{sol}}}{C_{\text{Sc}} + C_{\text{Sol}}} \cong 1$. In this case, a change in the overpotential only affects the potential drop in the depletion layer. The surface energy levels of the semiconductor remain at the same relative position with respect to the electron levels of the redox system, (see Figure 2b for an *n*-type semiconductor). The probability of tunneling through the Helmholtz layer is unaltered by a change of the overpotential, in contrast with a metal electrode. A change of the overpotential only affects the density of free carriers at the surface. Applying Eq. 62 for the surface, $x = 0$, we find for an *n*-type semiconductor that

$$n(0) = n^{\text{eq}}(0)e^{(\mu_e - \mu_e^{\text{eq}})/k_B T} \quad (121)$$

It is concluded that if $\frac{C_{\text{sol}}}{C_{\text{Sc}} + C_{\text{Sol}}} \cong 1$ holds, the anodic current density remains

equal to the exchange current density at equilibrium, and that the cathodic current density increases exponentially with $\mu_e - \mu_e^{\text{eq}}$. In the framework of the phenomenological treatment presented in Section 4.7, this would mean that $\alpha_a = 0$, and that $\alpha_c = 1$. The relationship between the current density j and the overpotential $\mu_e - \mu_e^{\text{eq}}$ is similar to that observed with a semiconductor/metal diode junction. In the literature, this is referred to as “ideal behavior”. Extensive research has been devoted to the electrochemical kinetics of semiconductor/electrolyte junctions, with a large variety of semiconductors and simple redox systems in aqueous and non-aqueous solvents being looked at. Only in a minority of cases were strong indications found for ideal behavior [15, 25, 26]. This is not unexpected, since the activation energy for electron exchange at equilibrium can be large, and even a small density of surface states may lead to an alternative pathway for exchange.

Several models have been proposed for the electrochemical kinetics if surface states are involved [15, 25]. They merely differ in their assumptions made to simplify the problem. A change in the occupation of the surface electron levels changes the potential drop over the depletion and Helmholtz layers. One should realize that then both the density of free carriers at the surface and the tunneling probability per electron changes with the overpotential. A complete treatment was presented in [15], for mono-energetic surface states, and in [27], assuming surface states distributed over the band gap. Here, we present results for surface states confined to a small energy range (Figure 29). The cathodic and anodic current density corresponding to direct and surface-state-mediated transfer are shown in Figure 29 (top

D. Vanmaekelbergh

Figure 29. Calculated current-potential characteristics for direct (dashed lines, $0/\text{cm}^2$) and surface state mediated electron transfer between an n -type semiconductor electrode and a simple redox system. The plots show the transition from ideal diode behavior to metallic behavior with increasing density of surface states at around the Fermi-level of the solid (indicated in the figures). This is also clear from the plots below, which show the change of the interfacial potential drop over the Helmholtz-layer (here denoted as $\Delta\phi_H$) with respect to the total change of the interfacial potential drop (here denoted as $\Delta\phi$). Results from D. Vanmaekelbergh, *Electrochim. Acta* 42, 1121 (1997).

part) as a function of $\mu_e - \mu_e^{\text{eq}}$. In Figure 29 (bottom), the change of the potential drop over the Helmholtz layer, $\phi_S - \phi_{\text{Sol}}$, referred to the total change of the interfacial potential drop $\phi - \phi_{\text{Sol}}$ is shown. It can be seen that the j vs $\mu_e - \mu_e^{\text{eq}}$ relationship changes from ideal diode behavior to that typical for a metal electrode if the effective density of surface states is gradually increased. It is also clear that surface states enhance the rate of electron exchange at equilibrium considerably.

5 Proton-Coupled Electron Transfer

Sharon Hammes-Schiffer

5.1 Introduction

Proton-coupled electron transfer (PCET) reactions play a vital role in a wide range of chemical and biological processes. For example, PCET is required for the conversion of energy in photosynthesis [1] and respiration [2]. In particular, the coupling between proton motion and electron transfer is involved in the pumping of protons across biological membranes in photosynthetic reaction centers [1] and in the conduction of electrons in cytochrome c [3]. In addition to biological processes, PCET is also important in electrochemical processes [4, 5] and in solid state materials [6].

Recently, a number of experiments on model PCET systems have been performed. Nocera and coworkers designed an experimental approach to photoinduce electron transfer within an electron donor–acceptor pair juxtaposed by a proton-transfer interface [7–9]. They have studied a variety of complexes, including a system in which an electron is transferred from a Ru^{II} polypyridine complex to dinitrobenzene through an amidinium–carboxylate interface [9]. Their results indicate that the electron transfer reaction is strongly affected by the proton interface and that in some cases a proton is transferred along with the electron. Meyer and coworkers have performed kinetic isotope effect studies on a range of oxoruthenium polypyridyl complexes [10]. Their experiments indicate that reactions based on the Ru^{IV} –oxo group often involve PCET. In addition, Thorp and coworkers have studied the effects of substitutions for reactions involving oxoruthenium [11]. These types of experimental studies on model PCET systems are becoming more prevalent as the important role of PCET in chemistry and biology is recognized.

The formulation of a theory for PCET is particularly challenging because of the disparate timescales involved. The description of the solute must accurately incorporate the quantum mechanical behavior of the solute electrons involved in both proton transfer (PT) and electron transfer (ET) and the transferring proton(s). The description of the solvent must include the effects of both electronic and inertial

polarization. In this chapter, electronic polarization refers to the solvent response assumed to be instantaneous, and inertial polarization refers to the non-instantaneous solvent response (e.g., nuclear reorientation and translation). As a result of these complexities, the theory of PCET has not been developed as extensively as the theory of single ET. To date, two distinct theoretical formulations for PCET have been proposed. The first was developed by Cukier [7, 12], and the second was developed by Soudackov and Hammes-Schiffer [13, 14]. This chapter centers on the second theoretical formulation, which is based on a multistate continuum theory. The first formulation will be discussed only briefly for comparison.

In the theory of PCET developed by Soudackov and Hammes-Schiffer, the solute is described with a multistate valence bond (VB) model, the solvent is represented as a dielectric continuum, and the active electrons and transferring proton(s) are treated quantum mechanically on equal footing. This theory provides free energy surfaces that depend on a set of scalar solvent variables corresponding to the individual charge transfer reactions. Thus, this theory is a multidimensional analog of the standard Marcus theory for single electron transfer. For processes involving significant inner-sphere (i.e., solute) reorganization, the effects of solute intramolecular vibrations can be incorporated into the formulation. The input quantities required for this theory are gas phase valence bond matrix elements that can be fit to quantum chemistry calculations and solvent reorganization energy matrix elements that can be calculated with electrostatic continuum methods.

Dielectric continuum theory has been applied to single ET and single PT reactions throughout the literature [4, 5, 15–22]. The most basic description of a single-charge transfer reaction is a two state VB model. As mentioned above, in this chapter the Born–Oppenheimer approach is adopted for the separation of solvent and solute electronic timescales (i.e., the solvent electrons are assumed to respond instantaneously to the solute electrons) [23]. In this case, the free energy curves are obtained as functions of a single scalar solvent variable representing the difference in interaction energies of the VB states with the solvent inertial polarization field. Various limits of single ET and single PT reactions have been thoroughly investigated. For example, single charge transfer reactions may be electronically adiabatic or non-adiabatic, where electronically adiabatic refers to the limit in which the solute electrons respond instantaneously to the inertial polarization of the solvent. Moreover, single PT reactions may be vibrationally adiabatic or non-adiabatic, where vibrationally adiabatic refers to the limit in which the transferring proton(s) respond instantaneously to the inertial polarization of the solvent. Rate expressions have been derived for these various limits.

The application of multistate continuum theory to PCET [13] is analogous to the previous applications to single charge transfer reactions. The most basic description of a PCET reaction involving one electron and one proton is a four-state VB model derived by combination of the two-state VB models for single ET and single PT reactions. Within this four-state VB model, the mixed electronic/proton vibrational free energy surfaces are obtained as functions of two scalar solvent variables corresponding to ET and PT. The adiabatic and non-adiabatic limits with respect to the ET electrons, PT electrons, and transferring proton have been considered. Both the ET and the PT electrons correspond to valence electrons of the solute: the ET

electrons are those involved in the change in charge distribution when the electron transfers, and the PT electrons are those involved in the breaking and forming of bonds when the proton transfers. Typically PCET reactions involve electronically adiabatic PT. In this case the four-state VB model can be transformed into a two-state VB model. Even in this two-state VB model, however, the free energy surfaces depend on two scalar solvent variables corresponding to ET and PT. In the limit of electronically non-adiabatic ET, the Golden Rule may be applied to these two-dimensional free energy surfaces for obtaining rate expressions.

The multistate continuum theory may be further extended for investigations of PCET reactions involving more than two charge transfer reactions. For example, a PCET reaction involving one electron and two protons is described by an eight-state VB model. In the limit of electronically adiabatic PT, this eight-state VB model can be transformed to a two-state VB model. In either case, however, the free energy surfaces are obtained as functions of three scalar solvent variables corresponding to the ET reaction and the two PT reactions.

An outline of this chapter is as follows. In Section 5.2, the basic two-state dielectric continuum theory for single ET and single PT reactions is described. The purpose of this section is to lay the groundwork for the future sections and to point out the important issues relevant to PCET reactions. In Section 5.3, the multistate continuum theory formulation for PCET reactions is presented. First, the general four-state VB model is presented and then the two-state VB model for the specific case of electronically adiabatic PT is presented. A discussion of the incorporation of inner-sphere reorganization and the extension to more than two charge transfer reactions is also included in this section. In the last part of this section, the theory of Cukier and coworkers is briefly discussed for comparison. In Section 5.4, applications of the multistate continuum theory formulation are discussed. The procedure for calculating the required input quantities is described, and the initial application to experimentally studied PCET through asymmetric salt bridges is discussed. In Section 5.5, the effects of specific solute and solvent properties on the rates and mechanisms of PCET are summarized. Future directions are discussed in Section 5.6.

5.2 Continuum Theory for Single Charge Transfer

In dielectric continuum theory, the solute density is placed in a cavity embedded in a dielectric continuum solvent characterized by the electronic and inertial dielectric constants ϵ_∞ and ϵ_o , respectively. Typically, the solvent polarization potential field is assumed to respond linearly to the change in solute charge density. The free energy of the system for fixed solute nuclei is a functional of the solvent inertial polarization potential field $\phi_{\text{in}}(\mathbf{r})$:

$$\mathcal{U}[\phi_{\text{in}}] = \mathcal{S}[\phi_{\text{in}}] + \mathcal{W}[\phi_{\text{in}}] \quad (1)$$

where $\mathcal{S}[\phi_{\text{in}}]$ is the self-energy of the solvent inertial polarization potential and $\mathcal{W}[\phi_{\text{in}}]$ includes the gas phase solute energy and the solute–solvent interaction energy. The interaction term can be expressed in terms of the solute electronic wavefunction Ψ as

$$\mathcal{W}[\phi_{\text{in}}] = \langle \Psi | \mathcal{H} | \Psi \rangle \quad (2)$$

where the Hamiltonian operator \mathcal{H} is a sum of the gas phase solute Hamiltonian and the interaction of the solute charge density with the solvent.

For charge transfer reactions, the solute electronic wavefunction is expanded in a basis of VB (also denoted “diabatic”) charge transfer states ψ_i :

$$\Psi = \sum_i c_i \psi_i \quad (3)$$

In this case, the free energy can be expressed in terms of a set of scalar solvent variables representing the interaction energies of the densities of the VB states with the solvent. If the off-diagonal densities are neglected, the required number of scalar solvent variables is one less than the number of included VB states with linearly independent densities [20]. The remainder of this section describes the application of this general approach to single ET and single PT and points out the issues relevant to PCET.

5.2.1 Single-Electron Transfer

The most basic ET system is represented by a two-state VB model with electronic VB states defined as

$$\begin{aligned} (1) \quad & \text{D}_e^\ominus \text{A}_e \\ (2) \quad & \text{D}_e \text{A}_e^\ominus \end{aligned} \quad (4)$$

where the symbols D_e and A_e represent a general electron donor and acceptor. In this model, the free energy can be expressed in terms of a single solvent coordinate z_e , which represents the difference in interaction energy of the two VB states with the inertial polarization field $\phi_{\text{in}}(\mathbf{r})$ of the solvent. Thus,

$$z_e = \int d\mathbf{r} [\rho_{22}(\mathbf{r}) - \rho_{11}(\mathbf{r})] \phi_{\text{in}}(\mathbf{r}) \quad (5)$$

where $\rho_{ii}(\mathbf{r})$ is the total charge density of VB state i . This type of scalar solvent coordinate has been used throughout the literature for the description of single electron transfer reactions [18, 19].

The VB matrix corresponding to the free energy given in Eq. 1 is

$$\mathbf{H}(z_e) = \mathcal{S}(z_e)\mathbf{I} + \mathbf{H}_o + \begin{pmatrix} 0 & 0 \\ 0 & z_e \end{pmatrix} \quad (6)$$

The first term, $\mathcal{S}(z_e)$, is the transformed self-energy of the solvent inertial polarization and is expressed as

$$\mathcal{S}(z_e) = \frac{1}{2t'_{22}}(z_e + t'_{12})^2 - \frac{1}{2}t'_{11} \quad (7)$$

The inertial reorganization energy matrix elements t'_{ij} are defined as

$$t'_{ij} = -\int d\mathbf{r} v_{ij}(\mathbf{r})[\hat{K}(\varepsilon_o) - \hat{K}(\varepsilon_\infty)]v_{ii}(\mathbf{r}) \quad (8)$$

where $\hat{K}(\varepsilon)$ is the dielectric Green function [24] for the medium with dielectric constant ε and

$$\begin{aligned} v_{11}(\mathbf{r}) &= \rho_{11}(\mathbf{r}) \\ v_{22}(\mathbf{r}) &= \rho_{22}(\mathbf{r}) - \rho_{11}(\mathbf{r}) \end{aligned} \quad (9)$$

The second term \mathbf{H}_o has matrix elements

$$(H_o)_{ij} = (h_o)_{ij} - \frac{1}{2}t_{ii}^{(\infty)}\delta_{ij} \quad (10)$$

where h_o is the gas phase solute Hamiltonian (which includes the kinetic energy of the solute electrons) and

$$t_{ij}^{(\infty)} = -\int d\mathbf{r} \rho_{ji}(\mathbf{r})\hat{K}(\varepsilon_\infty)\rho_{ii}(\mathbf{r}) \quad (11)$$

is the electronic reorganization energy matrix element that accounts for the interaction of the solute with the electronic polarization of the solvent (within the Born–Oppenheimer approximation). The third term in Eq. 6 represents the interaction of the solute with the inertial polarization of the solvent.

The VB matrix given in Eq. 6 involves only a single solvent coordinate z_e . In the derivation of this expression, the off-diagonal densities are neglected and a coordinate transformation eliminates one of the diagonal densities. Due to this coordinate transformation, the transformed self-energy $\mathcal{S}(z_e)$ given in Eq. 7 is the sum of the actual self-energy of the solvent inertial polarization and the term $\int d\mathbf{r} \rho_{11}(\mathbf{r})\phi_{in}(\mathbf{r})$, which represents the interaction of the density of VB state 1 with the inertial polarization of the solvent. As a result, this interaction is not included in the third term of Eq. 6.

Figure 1. Schematic illustration of the diabatic (solid) and adiabatic (long-dashed) electronic free energy curves as functions of the solvent coordinate z_e for a single electron transfer reaction. The Marcus theory quantities ΔG° and λ are indicated.

The diabatic free energy curves are the diagonal elements $H_{11}(z_e)$ and $H_{22}(z_e)$ of the matrix \mathbf{H} given in Eq. 6. These curves are parabolas with minima at $z_e^R = -t'_{12}$ and $z_e^P = -t'_{12} - t'_{22}$ and an intersection point at $z_e^\ddagger = (H_o)_{11} - (H_o)_{22}$. Figure 1 is a schematic illustration of these two parabolas and indicates the standard Marcus theory parameters λ and ΔG° [4, 15]. The adiabatic free energy curves can be calculated if the matrix \mathbf{H} is diagonalized, as shown by the dashed lines in Figure 1. Although the lowest adiabatic curve is a double well in Figure 1, it could be a single well in the Marcus inverted region (defined as $-\Delta G^\circ > \lambda$) or in the limit of very large coupling between the VB states. Note that in this formulation, the reorganization energy and free energy of reaction are

$$\lambda = t'_{22}/2 \quad (12)$$

$$\Delta G^\circ = (H_o)_{22} - (H_o)_{11} + \Delta G^{\text{solv}} \quad (13)$$

where

$$\Delta G^{\text{solv}} = -\frac{1}{2}t'_{22} - t'_{12} \quad (14)$$

is the difference in the equilibrium inertial solvation energies of states 1 and 2. [Note that the electronic solvation energy is included in the term $(H_o)_{22} - (H_o)_{11}$.] It is straightforward to prove that, in the limit of weak coupling, the standard Marcus barrier formula is obtained. Rate expressions have been derived for electron transfer in both the adiabatic and non-adiabatic limits. The adiabatic limit of ET refers to the situation in which the solute electrons respond instantaneously to the inertial solvent motion, and the reaction occurs on the lowest adiabatic free energy curve. The non-adiabatic limit of ET corresponds to weak coupling between the diabatic electronic states, and the upper adiabatic curve is involved.

The non-adiabatic limit of ET is most relevant to typical PCET reactions. In the non-adiabatic limit, application of the Golden Rule to the diagonal elements of the VB matrix given in Eq. 6 leads to the rate expression [16, 17, 25, 26].

$$k_{12} = \frac{2\pi}{\hbar} |(h_o)_{12}|^2 (4\pi\lambda k_B T)^{-1/2} \exp[-(\Delta G^\circ + \lambda)^2 / (4\lambda k_B T)] \quad (15)$$

An analogous rate expression has been derived for non-adiabatic electron transfer in the presence of an inner-sphere solute mode that is not coupled to the solvent. In this case, the VB matrix is the same as that in Eq. 6, with a dependence of the diagonal gas-phase matrix elements $(h_o)_{ii}$ on an inner-sphere solute mode q . The inner-sphere vibrational wave functions are calculated for each diabatic electronic state by a solution of the Schrödinger equation:

$$[T_q + (H_o)_{ii}(q)]\phi_\mu^{(i)}(q) = \varepsilon_\mu^{(i)} \phi_\mu^{(i)}(q) \quad (16)$$

where T_q is the kinetic energy of the inner-sphere solute mode. Application of the Golden Rule to this system leads to the rate expression [27, 28]:

$$k_{12} = \frac{2\pi}{\hbar} |(h_o)_{12}|^2 (4\pi\lambda k_B T)^{-1/2} \sum_\mu \rho_{1\mu} \sum_v |\langle \phi_\mu^{(1)} | \phi_v^{(2)} \rangle_q|^2 \\ \times \exp[-(\varepsilon_v^{(2)} - \varepsilon_\mu^{(1)} + \Delta G^{\text{solv}} + \lambda)^2 / (4\lambda k_B T)] \quad (17)$$

where \sum_μ and \sum_v indicate a summation over the vibrational states for diabatic state 1 and 2, respectively, $\langle \rangle_q$ indicates integration over the inner-sphere mode q , and $\rho_{1\mu}$ is the Boltzmann factor for state 1μ . Note that this equation is valid only if the inner-sphere mode is not coupled to the solvent. In general, the transferring proton in PCET reactions is coupled to the solvent. Thus, the application of this equation with the identification of the transferring proton as the inner-sphere mode is not valid for general PCET reactions.

5.2.2 Single Proton Transfer

A single proton transfer reaction can be represented by a two-state VB model with electronic VB states defined as

where the symbols D_p and A_p represent a general proton donor and acceptor and H represents the transferring proton. For simplicity, all solute nuclei are assumed to be fixed except the transferring H atom, which has a coordinate r_p . In this model, the free energy can be expressed in terms of a single solvent coordinate z_p defined as

$$z_p = \int d\mathbf{r} [\rho_{bb}(\mathbf{r}) - \rho_{aa}(\mathbf{r})] \phi_{\text{in}}(\mathbf{r}) \quad (19)$$

The VB matrix corresponding to the free energy is

$$\mathbf{H}(r_p, z_p) = \mathcal{S}(r_p, z_p) \mathbf{I} + \mathbf{H}_o(r_p) + \begin{pmatrix} 0 & 0 \\ 0 & z_p \end{pmatrix} \quad (20)$$

where all definitions are analogous to those given for single ET except for the dependence of \mathcal{S} and \mathbf{H}_o on the proton coordinate r_p . (Again the off-diagonal densities are neglected.) The electronically diabatic surfaces $H_{ii}(r_p, z_p)$ are parabolic along the z_p coordinate. A proton transfer reaction may be electronically adiabatic or electronically non-adiabatic, where electronically adiabatic refers to the situation in which the solute electrons respond instantaneously to the proton and solvent.

In the electronically non-adiabatic limit, the proton vibrational states can be calculated for each diabatic electronic state (i.e., each diagonal element of the matrix \mathbf{H} defined in Eq. 20). If the r_p -dependence of the self energy is neglected, this leads to two sets of shifted parabolas (with the same frequencies) along z_p , corresponding to electronic states a and b . In the limit of weak coupling, the rate expression for electronically non-adiabatic proton transfer is analogous to that given in Eq. 17 [except that $(h_o)_{ab}$ may depend on r_p and thus is included in the integration over r_p as $|\langle \phi_\mu^{(a)} | (h_o)_{ab}(r_p) | \phi_\nu^{(b)} \rangle_p|^2$].

For typical PCET reactions, the proton transfer reaction is electronically adiabatic. The electronically adiabatic surface is the lowest eigenvalue of $\mathbf{H}(r_p, z_p)$, expressed as

$$E(r_p, z_p) = \mathcal{S}(r_p, z_p) + \frac{1}{2} \left\{ (H_o)_{aa}(r_p) + (H_o)_{bb}(r_p) + z_p - \sqrt{[z_p + (H_o)_{bb}(r_p) - (H_o)_{aa}(r_p)]^2 + 4(H_o)_{ab}(r_p)^2} \right\} \quad (21)$$

In general, this surface is not parabolic along the z_p coordinate.

An electronically adiabatic proton transfer reaction may be either vibrationally adiabatic or vibrationally non-adiabatic. Vibrationally adiabatic refers to the situation in which the proton responds instantaneously to the solvent, while vibrationally non-adiabatic refers to the opposite limit. The adiabatic proton vibrational wave functions are calculated if the Schrödinger equation is solved for fixed values of z_p :

$$[T_p + E(r_p, z_p)] \phi_\mu(r_p; z_p) = \varepsilon_\mu(z_p) \phi_\mu(r_p; z_p) \quad (22)$$

where T_p is the kinetic energy of the proton mode. (Note that if the dependence of the transformed self-energy \mathcal{S} on the proton coordinate r_p is negligible, the change in free energy $E(r_p, z_p)$ along r_p is nearly equivalent to the change in potential energy along r_p .) Figure 2a is a schematic illustration of the energies $\varepsilon_\mu(z_p)$ of the two lowest adiabatic proton vibrational states for a typical symmetric single proton transfer reaction. The corresponding energies along the proton coordinate r_p for specified values of z_p are depicted in Figure 2b. If the reaction is vibrationally

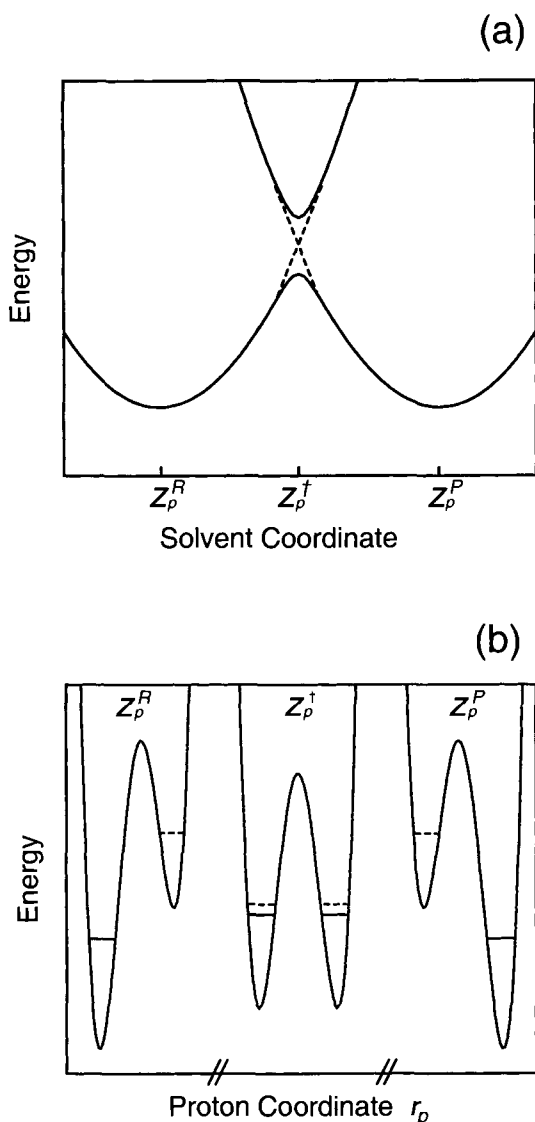

Figure 2. (a) Schematic illustration of the adiabatic (solid) and diabatic (dashed) vibrational free energy curves as functions of the solvent coordinate z_p for a symmetric single proton transfer reaction. (b) Potential energy curves as functions of the proton coordinate r_p for three specific values of the solvent coordinate z_p indicated in (a).

adiabatic, the reaction progresses on the lower curve and the rate could be calculated with an analog of the adiabatic ET rate expression. If the reaction is vibrationally non-adiabatic, the upper state is involved. The calculation of rates for vibrationally non-adiabatic reactions involves the definition of localized diabatic proton vibrational states (with energies indicated as dashed lines in Figure 2a) and the application of the Golden Rule to these vibrationally diabatic states [21].

The vibrationally adiabatic proton wave functions provide the most useful description for PCET reactions. For typical single proton transfer reactions, the lowest adiabatic vibrational state is a double well along z_p , as shown in Figure 2a. In gen-

eral, however, the lowest adiabatic vibrational state need not be a double well along z_p . For example, the lowest adiabatic vibrational state could be a single well along z_p if the potential energy along r_p is a single well. A single well potential energy along r_p could arise due to a large difference between the energies of the two VB states, a large coupling between the two VB states, or a short distance between the proton donor and acceptor. Moreover, the lowest adiabatic vibrational state could be a single well along z_p if the potential energy along r_p is a double well but the reorganization energy is very small. As will be discussed below, the free energy surfaces for PCET reactions are typically single wells along the z_p coordinate for the relevant energies. This single well character arises from the small reorganization energy for PT relative to the energy difference between the PT states.

5.3 Multistate Continuum Theory for Proton-Coupled Electron Transfer

5.3.1 Four-State Formulation

The most basic PCET system can be represented by a four-state VB model with electronic VB states defined as

$$\begin{aligned}
 (1a) \quad & D_e^\ominus - {}^\oplus D_p \text{ H} \cdots \cdots A_p^\ominus - A_e \\
 (1b) \quad & D_e^\ominus - D_p \cdots \cdots \text{H} A_p - A_e \\
 (2a) \quad & D_e - {}^\oplus D_p \text{ H} \cdots \cdots A_p^\ominus - A_e^\ominus \\
 (2b) \quad & D_e - D_p \cdots \cdots \text{H} A_p - A_e^\ominus.
 \end{aligned} \tag{23}$$

The notation for these VB states is consistent with the notation used in the above discussion of single ET and single PT. Thus, a and b indicate the proton transfer (PT) state, and 1 and 2 indicate the electron transfer (ET) state. As above, all solute nuclei are assumed to be fixed except the transferring H atom, which has a coordinate r_p .

In this model, the free energy can be expressed in terms of the proton coordinate r_p and two scalar solvent coordinates z_p and z_e corresponding to PT and ET, respectively. Each scalar solvent coordinate represents the difference in interaction energy of the two VB states involved in the charge transfer reaction with the inertial polarization field $\phi_{\text{in}}(\mathbf{r})$ of the solvent. Thus,

$$\begin{aligned}
 z_p &= \int d\mathbf{r} [\rho_{1b,1b}(\mathbf{r}) - \rho_{1a,1a}(\mathbf{r})] \phi_{\text{in}}(\mathbf{r}) \\
 z_e &= \int d\mathbf{r} [\rho_{2a,2a}(\mathbf{r}) - \rho_{1a,1a}(\mathbf{r})] \phi_{\text{in}}(\mathbf{r})
 \end{aligned} \tag{24}$$

where $\rho_{ii}(\mathbf{r})$ is the total charge density of VB state i . These scalar solvent coor-

dinates are analogous to the standard solvent coordinate used for the description of single ET and single PT reactions. In general, a four-state VB model would include three solvent coordinates, where the third solvent coordinate is defined as

$$z_{ep} = \int d\mathbf{r} [\rho_{2b,2b}(\mathbf{r}) - \rho_{1a,1a}(\mathbf{r})] \phi_{in}(\mathbf{r}) \quad (25)$$

As shown in Ref. [13], however, for the PCET four-state VB model defined in Eq. 23

$$z_{ep} = z_p + z_e \quad (26)$$

due to a linear dependency among the VB state densities. Thus, the only linearly independent scalar solvent coordinates in this model are z_p and z_e . (The off-diagonal densities are neglected.)

The VB matrix corresponding to the free energy is

$$\mathbf{H}(r_p, z_p, z_e) = \mathcal{S}(r_p, z_p, z_e) \mathbf{I} + \mathbf{H}_o(r_p) + \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & z_p & 0 & 0 \\ 0 & 0 & z_e & 0 \\ 0 & 0 & 0 & z_p + z_e \end{pmatrix} \quad (27)$$

The transformed self-energy of the solvent inertial polarization field can be expressed as

$$\mathcal{S}(r_p, z_p, z_e) = \frac{1}{2} \sum_{i,j=1b,2a} \{ [y'_i + t'_{1a,i}(r_p)] [\mathbf{t}'_i(r_p)^{-1}]_{i,j} [y'_j + t'_{1a,j}(r_p)] \} - \frac{1}{2} t'_{1a,1a}(r_p) \quad (28)$$

where the summation runs over valence bond states $1b$ and $2a$, the truncated reorganization energy matrix \mathbf{t}'_i has dimensions 2×2 corresponding to these two states, and $(z_p, z_e) \equiv (y'_{1b}, y'_{2a})$. (The $1a$ state is eliminated through a coordinate transformation and the $2b$ state is eliminated due to the linear dependency among the solvent coordinates.) The inertial reorganization energy matrix elements t'_{ij} are defined in Eq. 8, where in this case

$$\begin{aligned} v_{1a,1a}(\mathbf{r}) &= \rho_{1a,1a}(\mathbf{r}) \\ v_{ii}(\mathbf{r}) &= \rho_{ii}(\mathbf{r}) - \rho_{1a,1a}(\mathbf{r}) \quad (i = 1b, 2a, 2b). \end{aligned} \quad (29)$$

The matrix elements of the Hamiltonian $\mathbf{H}_o(r_p)$ are defined in Eq. 10. The last term in Eq. 27 represents the interaction of the solute with the inertial polarization potential field of the solvent. (As discussed above, the transformed self-energy includes the interaction of the VB state $1a$ with the inertial polarization of the solvent.)

One important result derived from this theoretical formulation is that the reorganization energy for PCET is not simply the sum of the reorganization energies for

PT and ET. Analogous to the situation discussed above for single ET, the reorganization energy for a reaction from the reference VB state $1a$ to VB state i is

$$\lambda_i = t'_{ii}/2 \quad (30)$$

As proven in Ref. [13],

$$\lambda_{2b} = \lambda_{1b} + \lambda_{2a} + t'_{1b,2a} \quad (31)$$

where λ_{2b} , λ_{1b} , and λ_{2a} denote the reorganization energies for PCET, PT, and ET, respectively. The extra term $t'_{1b,2a}$ is due to the interaction of the density $v_{1b,1b}$ with the inertial polarization field caused by the density $v_{2a,2a}$ (or, equivalently, the reverse interaction).

The description of PCET reactions is particularly challenging due to the quantum mechanical behavior of the ET electrons, the PT electrons, and the transferring protons. The adiabatic mixed electronic/proton vibrational states are calculated when the following Schrödinger equation is solved for fixed solvent coordinates (z_p, z_e) :

$$H'(\mathbf{r}_e, r_p, z_p, z_e)\Phi_n(\mathbf{r}_e, r_p; z_p, z_e) = E_n(z_p, z_e)\Phi_n(\mathbf{r}_e, r_p; z_p, z_e) \quad (32)$$

where

$$H'(\mathbf{r}_e, r_p, z_p, z_e) = T_p + \mathcal{S} + \mathcal{H}. \quad (33)$$

Here \mathbf{r}_e represents the electron coordinates, T_p is the kinetic energy of the transferring proton, and \mathcal{S} and \mathcal{H} are defined in Eqs. 1 and 2 (and are represented in the VB basis by the matrix \mathbf{H} in Eq. 27). A convenient set of basis functions for the solution of Eq. 32 is

$$\xi_{i\mu}(\mathbf{r}_e, r_p; z_p, z_e) = \psi_i(\mathbf{r}_e; r_p, z_p, z_e)\phi_{\mu}^{(i)}(r_p; z_p, z_e) \quad (34)$$

where ψ_i is the electronic VB state i and $\phi_{\mu}^{(i)}$ is the corresponding proton vibrational state calculated if the one-dimensional Schrödinger equation is numerically solved:

$$[T_p + H_{ii}(r_p, z_p, z_e)]\phi_{\mu}^{(i)}(r_p; z_p, z_e) = \varepsilon_{\mu}^{(i)}(z_p, z_e)\phi_{\mu}^{(i)}(r_p; z_p, z_e). \quad (35)$$

Here $H_{ii}(r_p, z_p, z_e)$ is the diagonal element of the VB matrix given in Eq. 27. The matrix \mathbf{H}' for the basis set defined in Eq. 34 has matrix elements

$$H'_{i\mu, j\nu} = \delta_{ij}\delta_{\mu\nu}\varepsilon_{\mu}^{(i)}(z_p, z_e) + \langle \phi_{\mu}^{(i)} | H_{ij} | \phi_{\nu}^{(j)} \rangle_p (1 - \delta_{ij}) \quad (36)$$

where $\langle \rangle_p$ indicates integration over the proton coordinate r_p .

The adiabatic mixed electronic/proton vibrational surfaces can be calculate by the diagonalization of the matrix \mathbf{H}' along a two-dimensional grid of solvent coordinates

(z_p, z_e) . These surfaces are numerically exact solutions to Eq. 32 and include all non-adiabatic coupling among the ET electrons, the PT electrons, and the transferring proton. Furthermore, although these surfaces are electronically and vibrationally adiabatic with respect to the solvent coordinates, the non-adiabatic coupling vectors between the adiabatic mixed electronic/proton vibrational states (i.e., the electron-solvent and proton-solvent non-adiabatic couplings) can be calculated along the solvent grid [13].

If the PCET reaction involves electronically adiabatic ET and PT and is vibrationally adiabatic, the system moves on the lowest two-dimensional energy surface equivalent to the lowest eigenvalue of the matrix \mathbf{H}' . In this case, the rate could be calculated with the multidimensional generalization of the Grote-Hynes theory [29–31].

If the PCET reaction involves electronically non-adiabatic ET and PT, the system can be viewed in terms of electronically diabatic surfaces given by $\varepsilon_\mu^{(i)}(z_p, z_e)$, defined in Eq. 35. If the dependence of the self-energy on the proton coordinate r_p is neglected, these surfaces consist of four sets of shifted paraboloids (with identical frequencies) in the two-dimensional solvent space. These two-dimensional paraboloids are analogous to the one-dimensional parabolas for the two-state single ET theory described above. The coupling between a pair of paraboloids $i\mu$ and $j\nu$ is $\langle \phi_\mu^{(i)} | (h_o)_{ij} | \phi_\nu^{(j)} \rangle_p$. In the limit of small coupling, the Golden Rule can be applied when the rate expressions for reactions among these electronically diabatic states are calculated.

Typically, PCET reactions involve electronically adiabatic PT and electronically non-adiabatic ET. In this case, the mixed electronic/proton vibrational ET diabatic surfaces may be obtained if Eq. 32 is solved with the settings $(H_o)_{1a,2a} = (H_o)_{1a,2b} = (H_o)_{1b,2a} = (H_o)_{1b,2b} = 0$. The resulting surfaces consist of two sets of two-dimensional “paraboloids” (where the quotation marks indicate that these surfaces are not exactly parabolic along z_p) corresponding to ET states 1 and 2. For each ET state, the minima of the “paraboloids” are shifted slightly depending on the weights of PT states a and b . The couplings between pairs of “paraboloids” can be calculated with the aid of the full Hamiltonian matrix \mathbf{H}' with all off-diagonal elements included. In the limit of weak coupling, the Golden Rule can be used for obtaining a rate expression. A simplification of this important limit is presented in the next section.

5.3.2 Two-State Formulation

A two-state model is possible for PCET reactions that involve electronically adiabatic PT. This two-state model is convenient for the derivation of a rate expression in the limit of electronically non-adiabatic ET. The first step is to transform the VB basis set to another equivalent basis set. The new basis functions are defined to be the eigenvectors of the two matrices

$$\mathbf{H}_I(r_p, z_p) = \begin{pmatrix} (H_o)_{1a,1a}(r_p) & (H_o)_{1a,1b}(r_p) \\ (H_o)_{1b,1a}(r_p) & (H_o)_{1b,1b}(r_p) + z_p \end{pmatrix} \quad (37)$$

$$\mathbf{H}_{\text{II}}(r_p, z_p) = \begin{pmatrix} (H_o)_{2a,2a}(r_p) & (H_o)_{2a,2b}(r_p) \\ (H_o)_{2b,2a}(r_p) & (H_o)_{2b,2b}(r_p) + z_p \end{pmatrix} \quad (38)$$

If all four of the new basis states are included, the adiabatic mixed electronic/proton vibrational states are exactly the same as those obtained with the original four VB states. Moreover, the diabatic mixed electronic/proton vibrational states for the new basis states are exactly the same as the adiabatic states obtained with the settings $(H_o)_{1a,2a} = (H_o)_{1a,2b} = (H_o)_{1b,2a} = (H_o)_{1b,2b} = 0$ (as described at the end of the previous section).

If the reaction involves electronically adiabatic PT, there is a large splitting between the two eigenvalues for each of these matrices. In this case, the two basis states higher in energy are negligible, and the free energy can be described in terms of the two remaining wavefunctions

$$\Psi_{\text{I}}(r_p, z_p) = c_{1a}(r_p, z_p)\psi_{1a} + c_{1b}(r_p, z_p)\psi_{1b} \quad (39)$$

$$\Psi_{\text{II}}(r_p, z_p) = c_{2a}(r_p, z_p)\psi_{2a} + c_{2b}(r_p, z_p)\psi_{2b} \quad (40)$$

with corresponding energies

$$E_{\text{I}}(r_p, z_p) = \frac{1}{2} \left\{ (H_o)_{1a,1a}(r_p) + (H_o)_{1b,1b}(r_p) + z_p - \sqrt{[z_p + (H_o)_{1b,1b}(r_p) - (H_o)_{1a,1a}(r_p)]^2 + 4(H_o)_{1a,1b}(r_p)^2} \right\} \quad (41)$$

$$E_{\text{II}}(r_p, z_p) = \frac{1}{2} \left\{ (H_o)_{2a,2a}(r_p) + (H_o)_{2b,2b}(r_p) + z_p - \sqrt{[z_p + (H_o)_{2b,2b}(r_p) - (H_o)_{2a,2a}(r_p)]^2 + 4(H_o)_{2a,2b}(r_p)^2} \right\} \quad (42)$$

The matrix representing the free energy in this new basis set is

$$\mathbf{H}(r_p, z_p, z_e) = \mathcal{S}(r_p, z_p, z_e)\mathbf{I} + \begin{pmatrix} E_{\text{I}}(r_p, z_p) & V(r_p, z_p) \\ V(r_p, z_p) & E_{\text{II}}(r_p, z_p) \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ 0 & z_e \end{pmatrix} \quad (43)$$

where the coupling is expressed as

$$V(r_p, z_p) = c_{1a}(r_p, z_p)c_{2a}(r_p, z_p)(h_o)_{1a,2a} + c_{1b}(r_p, z_p)c_{2b}(r_p, z_p)(h_o)_{1b,2b} \\ + c_{1a}(r_p, z_p)c_{2b}(r_p, z_p)(h_o)_{1a,2b} + c_{1b}(r_p, z_p)c_{2a}(r_p, z_p)(h_o)_{1b,2a} \quad (44)$$

The proton vibrational states can be calculated for each of the two electronic states by solution of the Schrödinger equation

$$[T_p + H_{JJ}(r_p, z_p, z_e)]\phi_{\mu}^J(r_p; z_p, z_e) = \varepsilon_{\mu}^J(z_p, z_e)\phi_{\mu}^J(r_p; z_p, z_e) \quad J = \text{I, II} \quad (45)$$

where H_{JJ} is the diagonal element of the matrix given in Eq. 43. The resulting mixed electronic/proton vibrational states consist of the initial states $\Psi_I \phi_\mu^I$ with energies $\varepsilon_\mu^I(z_p, z_e)$ and the final states $\Psi_{II} \phi_\nu^{II}$ with energies $\varepsilon_\nu^{II}(z_p, z_e)$.

These ET diabatic free energy surfaces are parabolic along the z_e coordinate but are not exactly parabolic along the z_p coordinate, because of the complicated z_p -dependence of E_I and E_{II} and the averaging over the r_p coordinate for the different vibrational states. For example, in general, these surfaces could be double wells along the z_p coordinate, as found for single PT reactions. For typical PCET reactions, however, these surfaces have been found to be approximately parabolic along the z_p coordinate at the energies of interest. This approximately parabolic form results from the small reorganization energy for PT relative to the difference in energies of VB states 1a and 1b and VB states 2a and 2b. Even for symmetric PT interfaces, the transferring electron introduces significant asymmetry between PT states *a* and *b*. Moreover, the reorganization energy for PT is decreased by the presence of the relatively large electron donor and acceptor.

Figures 3–5 depict the energies $\varepsilon_\mu^I(z_p, z_e)$ and $\varepsilon_\nu^{II}(z_p, z_e)$ [in parts (a)] and the associated potential energy curves along r_p [in parts (b)] for model symmetric PCET

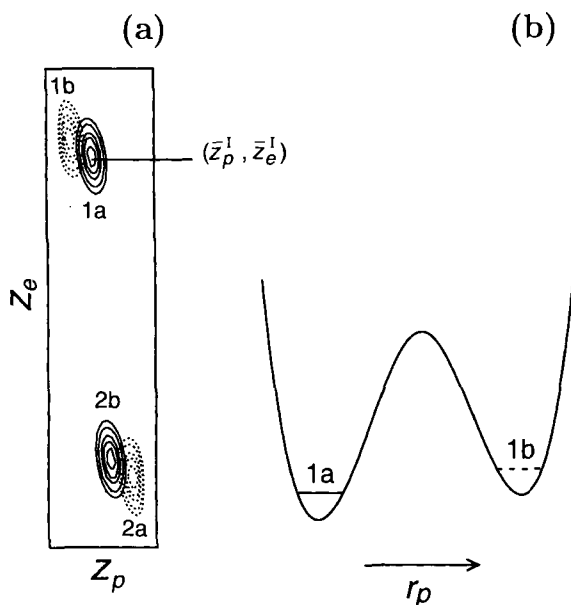

Figure 3. (a) The ET diabatic free energy surfaces as functions of the solvent coordinates z_p and z_e for a symmetric PCET reaction. For simplicity, only the lowest two mixed electronic/proton vibrational states are shown for each ET state. The two lowest energy states are solid while the two higher energy states are dashed. The free energy surfaces are labeled according to the dominant valence bond state. (b) The potential energy curve as a function of the proton coordinate r_p evaluated at $(\bar{z}_p^I, \bar{z}_e^I)$, the minimum of the lowest energy state in (a) corresponding to ET state 1. The lowest two proton vibrational adiabatic states are indicated on this potential energy curve.

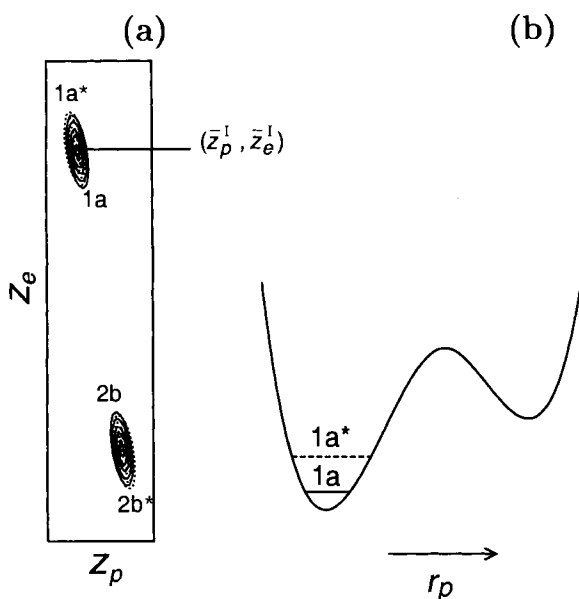

Figure 4. The same features as in Figure 3 are shown here, but for a different symmetric PCET reaction. The asterisks indicate excited vibrational states. Note that the two-dimensional plot contains four “paraboloids,” although two pairs are virtually identical.

Figure 5. The same features as in Figure 4 are shown here, but for a different symmetric PCET reaction. The $1a/1b$ ($2b/2a$) notation indicates a mixture of the $1a$ and $1b$ ($2a$ and $2b$) valence bond states, and the asterisks indicate excited vibrational states. Note that the two-dimensional plot contains four “paraboloids”, although two pairs are virtually identical.

reactions. These model systems, which consist of point charges placed in an ellipsoidal cavity embedded in a dielectric continuum, are described in detail in Ref. [32]. For simplicity, in parts (a), only the lowest two mixed electronic/proton vibrational free energy surfaces are shown for each ET state. These ET diabatic free energy surfaces are labeled according to the dominant VB state. Note that the energy scales for z_p and z_e are not the same, but, rather, the z_p axis is expanded by a factor of approximately four. In other words, the disparity between the lengths of the z_p and z_e axes should be approximately four times greater. The shifts of the “paraboloids” are smaller along z_p than along z_e , because proton transfer has a smaller solvent reorganization energy than that of electron transfer. In parts (b), the potential energy curves along the proton coordinate r_p are shown only for the solvent coordinates $(\bar{z}_p^1, \bar{z}_e^1)$, the minimum of the lowest energy “paraboloid” corresponding to ET state 1.

In Figure 3a, the “paraboloids” correspond to electronic states $1a$, $1b$, $2a$, and $2b$. This situation arises when the potential along the r_p coordinate (shown in Figure 3b) is slightly asymmetric, with a high barrier so that the lowest two vibrational states are virtually pure (i.e., localized) a and b PT states. Note that the minima for the “paraboloids” corresponding to the $1a$ and $1b$ states are shifted relative to each other. A transition from $1a$ to $2a$ corresponds to ET, while a transition from $1a$ to $2b$ corresponds to EPT (where both the electron and the proton are transferred).

In Figure 4a, the “paraboloids” correspond to electronic states $1a$, $1a^*$, $2b$, and $2b^*$, where the asterisks indicate excited vibrational states. This situation arises when the potential along the r_p coordinate (shown in Figure 4b) is very asymmetric so that the lowest two vibrational states are localized on the same side of the PT interface (in this case a for electronic state 1 and b for electronic state 2). Note that the minima for the “paraboloids” corresponding to the $1a$ and $1a^*$ states are virtually identical. The slight shift between these “paraboloids” is due to somewhat less purity of the $1a^*$ state.

In Figure 5a, the “paraboloids” correspond to electronic states $1a/1b$, $1a/1b^*$, $2b/2a$, and $2b/2a^*$. This situation arises when the potential along the r_p coordinate (shown in Figure 5b) has a low barrier (or no barrier) so that all vibrational states are mixtures of a and b PT states and are delocalized. Note that the minima for the $1a/1b$ and $1a/1b^*$ states are virtually identical. These examples illustrate that the multistate continuum theory provides a valuable framework for the analysis and interpretation of the wide range of behavior exhibited by PCET reactions.

Although the matrix in Eq. 43 is of the same form as the matrix in Eq. 6, which was used in two-state ET theory, these two matrices are fundamentally different because of the dependence of the PCET matrix on the second solvent coordinate z_p and the proton coordinate r_p . In the limit that \mathcal{S} and V are independent of r_p and that E_I , E_{II} , \mathcal{S} , and V are independent of z_p , the rate expression for non-adiabatic ET is the same for PCET as for single ET with an inner-sphere mode, given in Eq. 17. This limit corresponds to no coupling between the proton and solvent and is not valid for general PCET reactions. Thus, a new rate expression must be derived by the application of the Golden Rule to the PCET system described by the Hamiltonian given in Eq. 43. This application of the Golden Rule involves transitions between pairs of two-dimensional approximate paraboloids rather than pairs of one-dimensional parabolas.

Such a rate expression has been derived for PCET reactions satisfying well-defined conditions [33]. First, all of the relevant diabatic free-energy surfaces are assumed to be exact paraboloids with identical second derivatives obtained from the self-energy (i.e., the r_p -dependence of the self-energy and the nonlinear z_p -dependence of $E_I(r_p, z_p)$ and $E_{II}(r_p, z_p)$ are neglected). Second, the coupling $V_{\mu\nu}(z_p)$ is assumed to be independent of z_p for the relevant energies. Third, the coupling $V_{\mu\nu}(z_p)$ is assumed to be much smaller than the thermal energy $k_B T$. If these three assumptions are valid, then application of the standard methodology used to derive the non-adiabatic ET rate expression given in Eq. 15 leads to

$$k = \frac{2\pi}{\hbar} \sum_{\mu} P_{\mu}^I \sum_{\nu} V_{\mu\nu}^2 (4\pi\lambda_{\mu\nu}k_B T)^{-1/2} \exp\left\{-\frac{(\Delta G_{\mu\nu}^{\circ} + \lambda_{\mu\nu})^2}{4\lambda_{\mu\nu}k_B T}\right\} \quad (46)$$

where \sum_{μ} and \sum_{ν} indicate a sum over vibrational states associated with ET state 1 and 2, respectively, and P_{μ}^I is the Boltzmann factor for state $I\mu$. In this expression, the reorganization energy is defined as

$$\lambda_{\mu\nu} = \varepsilon_{\mu}^I(\bar{z}_p^{II\nu}, \bar{z}_e^{II\nu}) - \varepsilon_{\mu}^I(\bar{z}_p^{I\mu}, \bar{z}_e^{I\mu}) \quad (47)$$

the free energy difference is defined as

$$\Delta G_{\mu\nu}^{\circ} = \varepsilon_{\nu}^{II}(\bar{z}_p^{II\nu}, \bar{z}_e^{II\nu}) - \varepsilon_{\mu}^I(\bar{z}_p^{I\mu}, \bar{z}_e^{I\mu}) \quad (48)$$

and the coupling is defined as

$$V_{\mu\nu} = \langle \phi_{\mu}^I | V(r_p, z_p^{\dagger}) | \phi_{\nu}^{II} \rangle_p \quad (49)$$

where $(\bar{z}_p^{I\mu}, \bar{z}_e^{I\mu})$ and $(\bar{z}_p^{II\nu}, \bar{z}_e^{II\nu})$ are the solvent coordinates for the minima of $\varepsilon_{\mu}^I(z_p, z_e)$ and $\varepsilon_{\nu}^{II}(z_p, z_e)$, respectively, and z_p^{\dagger} is the PT solvent coordinate at the intersection point of the two paraboloids along the straight-line reaction path connecting the two minima. Note that typically $V_{\mu\nu}$ is much smaller than the thermal energy for the EPT mechanism even in the limit of electronically adiabatic ET due to the averaging of the coupling over the proton vibrational wavefunctions. Although the three assumptions mentioned above are not rigorously valid for the PCET formulation described in this chapter, they are approximately valid for many PCET reactions of interest. Thus, this rate expression allows the calculation of approximate rates for a wide range of PCET reactions. The derivation of more general rate expressions is a direction for the future.

The previous work of Cukier and coworkers [7, 12] differs from the formulation described in this chapter in a number of fundamental ways. In contrast to the multistate continuum theory described in this chapter, Cukier and coworkers did not calculate mixed electronic/proton vibrational free energy surfaces as functions of two solvent coordinates. Instead, they calculated “solvated proton potentials” obtained by the assumption that the inertial polarization of the solvent responds instantaneously to the proton position. (This is the limit opposite to the standard adiabatic limit of the fast proton vibrational motion responding instantaneously to

the slower inertial solvent motion.) Cukier and coworkers calculated adiabatic proton vibrational wave functions for the solvated proton potentials for the two relevant diabatic electronic states and calculated values for the reorganization energy for both ET and EPT with a five-site ellipsoidal model. They used Eq. 17 in conjunction with these two different reorganization energies to calculate two separate rates for ET and EPT. Note that the derivation of Eq. 17 is for a single ET reaction described by a single solvent coordinate z_e with an inner-sphere solute mode that is not coupled to the solvent. Thus, the direct application of this equation does not accurately account for the coupling of the proton to the solvent in PCET reactions.

5.3.3 Incorporation of Inner-Sphere Reorganization

Inner-sphere reorganization (i.e. solute reorganization) is important if the solute nuclear coordinates change significantly during the charge transfer process. Inner-sphere reorganization can be incorporated into the multistate continuum theory by the introduction of one or more inner-sphere reaction coordinates and by the parametrization of the gas phase Hamiltonian as a function of these inner-sphere reaction coordinates. If a single solute mode is mainly responsible for the inner-sphere reorganization energy, this mode is treated as the inner-sphere coordinate. If many solute modes are responsible for the inner-sphere reorganization energy, one (or possibly a few) collective inner-sphere reaction coordinates are defined. The collective inner-sphere reaction coordinate(s) are determined by geometry optimizations being performed for all VB states. The gas phase matrix elements are parametrized to reproduce the calculated energies of the VB states (or the associated adiabatic states) at these optimized geometries. In the simplest case, the term $\frac{1}{2}k_i(q - q_i)^2$ is added to each gas-phase matrix element $(h_o)_{ii}$, where q is the inner-sphere reaction coordinate, q_i represents the optimized solute geometry for valence bond state i , and k_i represents a frequency that is fit so that the calculated energies for state i are obtained at the optimized geometries for the other VB states.

Once the gas phase Hamiltonian is parametrized as a function of the inner-sphere reaction coordinate(s), the free energy is calculated as a function of the proton coordinate(s), the scalar solvent coordinates, and the inner-sphere reaction coordinate(s). Note that this approach assumes that the optimized geometries of the VB states are not significantly affected by the solvent. For proton transfer reactions, the proton donor-acceptor distance may be treated as an additional solute reaction coordinate that can be incorporated into the molecular mechanical terms describing the diagonal matrix elements $(h_o)_{ii}$ and, in some cases, the off-diagonal matrix elements $(h_o)_{ij}$. If the inner-sphere reaction coordinate represents a “slow” mode, it is treated in the same way as the solvent coordinates. As discussed throughout the literature, however, often the inner-sphere reaction coordinate must be treated quantum mechanically [27, 28]. In this case, the inner-sphere reaction coordinate is treated in the same way as the proton coordinate(s), and the vibrational wave functions depend explicitly on both the proton coordinate(s) and the inner-sphere reaction coordinate(s).

Figure 6. Model PCET systems investigated with the multistate continuum theory.

5.3.4 Extension to More than Two Charge-Transfer Reactions

This multistate continuum theory has been generalized for charge-transfer reactions involving N_e transferring electrons and N_p transferring protons. For this general case, the solute is represented by a VB model containing $2^{N_e+N_p}$ VB states. The free energies of the electronic states are expressed in terms of $N_e + N_p$ linearly independent scalar solvent coordinates and N_p proton coordinates (assuming that all other solute coordinates are fixed). The proton coordinates are treated quantum mechanically for the calculation of the adiabatic mixed electronic/proton vibrational free energy surfaces as functions of $N_e + N_p$ scalar solvent coordinates. (In this case, the calculation of the proton vibrational states may require the solution of a multi-dimensional rather than a single-dimensional Schrödinger equation.) If inner-sphere reorganization is significant, the effects of intramolecular solute vibrations are incorporated into the adiabatic states.

The systems depicted in Figure 6 are examples of PCET systems involving the transfer of one electron coupled to the motion of two protons. Although only one proton is expected to transfer in these systems, the electron transfer reaction could be coupled to the motion of both protons. These systems may be described with eight-state VB models. If the notation introduced above is used, the VB states are denoted $1aa$, $1ba$, $1ab$, $1bb$, $2aa$, $2ba$, $2ab$, $2bb$, where the first index indicates the ET state and the second and third indices indicate the PT state for the first and second proton transfer reactions, respectively. The free energy surfaces obtained with this model depend on three solvent variables, z_e , z_{p1} , and z_{p2} , corresponding to the electron transfer and the two proton transfer reactions. Another type of PCET reaction involving more than a single PT reaction is PCET along a hydrogen-bonding network (e.g., a chain of hydrogen-bonded water molecules). Such a mechanism is thought to be important in a wide range of proteins. Thus, the gen-

eralizability of the multistate continuum theory is a critical feature for the study of biologically relevant processes.

5.4 Applications of Proton-Coupled Electron Transfer in Solution

5.4.1 Calculation of Input Quantities

The input quantities required for the multistate continuum theory for PCET are the gas phase VB matrix elements, the inertial reorganization energy matrix, and the diagonal elements of the electronic reorganization energy matrix. In general, all of these quantities depend on the proton coordinate. The matrix elements of the gas phase Hamiltonian can be approximated by standard molecular mechanical terms fit to electronic structure calculations for the gas phase solute [34–36]. The reorganization energy matrix elements can be determined with standard electrostatic continuum methods for calculating the polarization potential fields resulting from a charge density in a cavity of arbitrary shape embedded in a dielectric continuum solvent [37]. Two-cavity models such as the FRCM method [38] could be utilized to obtain more accurate reorganization energy matrix elements.

5.4.2 Proton-Coupled Electron Transfer through Asymmetric Salt Bridges

The initial application of this multistate continuum theory was the investigation of PCET through asymmetric salt bridges [13]. The specific systems studied represent a donor–(amidinium–carboxylate)–acceptor salt bridge (DNOA) and the corresponding switched interface donor–(carboxylate–amidinium)–acceptor salt bridge (DONA), as shown in Figure 6. These theoretical investigations were motivated by experiments of Nocera and coworkers, who studied systems analogous to the DNOA and DONA systems depicted in Figure 6, except that the electron donors were $[(\text{tmbpy})_2\text{Ru}^{\text{II}}(\text{Mebpy}-\text{amH}^+)]^{3+}$ and $[(\text{tmbpy})_2\text{Ru}^{\text{II}}(\text{Mebpy}-\text{COO}^-)]^+$, respectively. (Here tmbpy = 3,3',4,4'-tetramethyl-2,2'-bipyridine, $\text{Mebpy}-\text{amH}^+$ = 4-methyl-2,2'-bipyridine-4'-amidinium, and $\text{Mebpy}-\text{COO}^-$ = 4-methyl-2,2'-bipyridine-4'-carboxylate.) In these experiments, the electron transfer reaction was initiated by laser excitation of the metal-to-ligand charge transfer transition of the Ru^{II} –polypyridyl complex. This photoexcitation promotes the transferring electron to the Mebpy ligand, from where it is transferred to the dinitrobenzoic acceptor through the salt-bridge interface. Nocera and coworkers found that the rate of electron transfer is approximately 10^2 times faster for the DONA interface than for the DNOA interface. This substantial difference between the rates for the two systems indicates that the proton transfer interface plays a significant role in the electron transfer reactions.

The initial theoretical studies on the DNOA and DONA systems were based on a four-state VB model, as given in Eq. 23. Thus, only one of the proton transfer

Figure 7. The two-dimensional ground state free energy surfaces for (a) DNOA and (b) DONA. The straight-line reaction paths are shown on the contour plots as dashed lines, and the minima are labeled according to the dominant VB states. Note that the z_p solvent coordinate is scaled by a factor of approximately four. (Reproduced from Ref. [14].)

reactions at the PT interface was included. The mixed electronic/proton vibrational free energy surfaces were obtained as functions of the two solvent coordinates z_p and z_e defined in Eq. 24. High-level electronic structure calculations were performed to obtain the gas phase energies of the active electronic states as functions of the proton coordinate r_p for the DNOA and DONA systems. The gas phase Hamiltonian matrix elements $(h_o)_{ij}(r_p)$ were represented as molecular mechanical terms parametrized to fit these gas phase energies. The reorganization energy matrix elements were calculated with a five-site ellipsoidal model. Figure 7 depicts the lowest-energy adiabatic surfaces for the DNOA and DONA systems, and Figure 8 depicts one-dimensional slices along a straight-line reaction path for these two-dimensional surfaces. [Note that for the DONA system, the reactant $1a$ state is so much higher in energy than the product $2a$ state that the $1a$ state does not correspond to a minimum on the lowest-energy adiabatic surface shown in Figure 7(b).]

The two-dimensional electron transfer diabatic free energy surfaces in Figure 7 have been analyzed with the Golden Rule rate expression given in Eq. 46. This analysis suggests that ET and EPT are possible for both systems, but ET is the dominant path due to significant overlap between the proton vibrational wave

Figure 8. Slices of the two-dimensional ET diabatic free energy surfaces along the reaction path indicated in Figure 7 for (a) DNOA and (b) DONA. The ET diabatic states are labeled according to the dominant VB states.

functions for the lowest 1a and 2a vibrational states. The relevant paths are endothermic for DNOA and exothermic for DONA, and the activation energy barriers are significantly higher for DNOA than for DONA. Thus, these free energy surfaces are consistent with the experimental result that the rate is faster for DONA than for DNOA. This initial application illustrates the power of the multistate continuum theory for elucidating PCET reactions. Recently this application has

been refined by implementing the two-cavity FBCM method [38] for calculating the reorganization energy matrix elements and by including both proton transfer reactions with an eight-state VB model.

5.5 Fundamental Principles of Proton-Coupled Electron Transfer

The multistate continuum theory for PCET provides a framework for the analysis of the effects of specific solute and solvent properties on the rates and mechanisms of PCET reactions. The properties of interest include the relative energies of the gas phase solute charge transfer states, the distance between the proton donor and acceptor, the distance between the electron donor and acceptor, and the solvent polarity. In Ref. [32], a comprehensive study of the effects of these physical properties on the rates, mechanisms, and kinetic isotope effects of PCET reactions is presented. Some of the predictions obtained from this study are discussed in this section.

The most important physical properties for determining both rates and mechanisms of PCET reactions are the relative energies of the solute charge transfer states. The rate is strongly affected by the relative energies of the ET states. If the energy of ET state 2 is decreased relative to the energy of ET state 1, the barrier for reaction decreases and the rate increases. When the Marcus inverted region is reached, this trend is reversed. The mechanism of PCET is strongly affected by the relative energies of the PT states. ET is favored as the energy of the $2a$ state is decreased relative to the $2b$ state, while EPT is favored as the energy of the $2b$ state is decreased relative to the $2a$ state.

The distance between the proton donor and acceptor also affects the rates and mechanisms of PCET reactions. As this distance decreases, the barrier along the proton coordinate r_p decreases and eventually disappears. As illustrated in Figures 3–5, the height of this barrier determines the number of localized proton vibrational states. In particular, if the barrier along the proton coordinate is very low or non-existent, the proton vibrational wave functions are mixtures of a and b , so the distinction between ET and EPT is unclear. For systems in which the potential is a double well along the proton coordinate, however, the rate of EPT decreases as the barrier along the proton coordinate increases due to the decrease of the overlap of the proton vibrational wave functions for the a and b states.

The distance between the electron donor and acceptor affects the rates and mechanisms of PCET reactions in two different ways. First, an increase in this distance results in a decrease in the coupling between ET states ($1a/2a$, $1a/2b$, $1b/2a$, $1b/2b$). In the limit of electronically non-adiabatic electron transfer, a decrease in this coupling results in a decrease in the rate. Moreover, as the distance between the electron donor and acceptor increases, the interaction between the proton and the electron decreases. Thus, for a symmetric PT system with an initial state of $1a$, EPT is favorable for short electron donor–acceptor distances and ET becomes equally favorable as this distance increases.

Finally, the solvent polarity will affect the rates and mechanisms of PCET re-

6 Relationship between Electron and Electronic Excitation Transfer

Piotr Piotrowiak

6.1 Introduction

In many molecular, biological and solid-state systems electron and electronic excitation transfer processes occur alongside one another. Frequently, they offer independent competing pathways for excited-state deactivation. More importantly, in certain instances, they are linked together as crucial steps of the same photo-conversion chain, for example, in the photosynthetic reaction centers, in which the elaborate arrays of antenna chromophores collect electronic energy and rapidly transfer it to the charge-separation site. The underlying formal link between these two phenomena is even more universal: both electronic excitation transfer (EET) and electron-transfer (ET) processes can be viewed as special cases of nonradiative decay of an electronic excited state. Consequently, the rate of both of these cases can be described by the appropriate variants of the Fermi “golden rule” [1]

$$k = (4\pi^2/h) \cdot |V|^2 \cdot \rho \quad (1)$$

with the differences lying only in the specific description of the electronic coupling V and the Franck–Condon density of states, ρ [2]. In both cases, the electronic coupling term, V , consists of the direct donor–acceptor interaction, as well as the component mediated by the intervening material (bridge, matrix, or solvent). The latter is usually conveniently treated by numerous variants of Kramers “superexchange” scheme [3]. Similarly, as the magnitude of the donor–acceptor interaction increases, both ET and EET shift from the weakly coupled (non-adiabatic) regime treated by the “golden-rule” expressions, to the strongly coupled, or adiabatic regime. For ET and EET in molecular systems, the treatment of the density of states, ρ , is also very similar, and typically involves partitioning of the relevant Frank–Condon factors into intramolecular and medium components. The objective of this short chapter is to emphasize the similarities between electron and electronic energy transfer processes and theories, as well as bring to the attention of the reader the important

aspects in which ET and EET differ from one another and may require diverse treatments. The author does not attempt to present a comprehensive review of the energy transfer literature and apologizes if many important contributions were not included among the illustrations of the discussed principles.

Despite the obvious connection between electron and electronic excitation transfer, the two fields of research have separate origins and for the most part evolved independently from one another. Charge-transfer investigations have their roots in electrochemistry and redox-reaction studies. Electron transfer has only since relatively recently frequently been associated with photoinduced processes. The early theory of charge transfer evolved from two directions [4]: classical rate theory and quantum-mechanical tunneling [5]. Not surprisingly, electronic excitation transfer was always associated with light, or more generally, radiation-induced phenomena. Its early theory, like that of charge transfer, stems from two independent sources, in this case the phenomenological description of quenching, and the time-dependent quantum mechanics of coupled systems [7]. Excitation-transfer studies often preceded their electron-transfer counterparts in terms of concepts or experimental execution, for example, the use of donors and acceptors dispersed in amorphous glasses [8], the application of steroids [9] and oligopeptides [10] as donor-acceptor bridges, and the investigation of the through-bond versus through-space electronic coupling [11] and orientation effects [12]. In other instances, for example, in the quest for the "Marcus inverted region," the lead clearly belonged to electron transfer [13]. In general, when it comes to studies on molecular donor-acceptor systems, both areas borrowed heavily from the more developed solid-state physics.

Very elegant experiments unequivocally proving the occurrence of electronic energy transfer were performed in 1922 and 1923 by Cario and Franck [14]. When a mixed vapor of mercury and thallium was irradiated with the mercury line at 253.67 nm, the emission lines of thallium could be observed in addition to the anticipated fluorescence spectrum of mercury. Since thallium cannot absorb 253.67-nm light, it must have been "sensitized" by the excited mercury atoms in order to produce the green fluorescence

A remarkably modern quantum-mechanical model of electronic energy transfer was introduced in 1928 by Kallmann and London [7]. In their approach, two atoms with energy levels E_k and F_k are described by stationary Schrödinger equations

$$[H, u_k] = E_k u_k; \quad [G, v_k] = F_k v_k \quad (2)$$

The interaction between the atoms is represented by a time-dependent potential W . This leads to a time-dependent Schrödinger equation describing the entire weakly coupled system:

$$[H, \psi] + [G, \psi] + W \cdot \psi - \frac{\hbar}{i} \cdot \frac{\partial \psi}{\partial t} = 0 \quad (3)$$

where ψ is the time-dependent wave function describing the entire system. This wave function is expanded in terms of the stationary eigenfunctions u_k and v_k :

$$\psi = fu_kv_je^{i/h(E_k+F_j)t} + gu_jv_ke^{i/h(E_j+F_k)t} + \dots \quad (4)$$

where E_k , F_k are the energies of the respective stationary states, and f and g are slowly varying functions of time. This last assumption leads to the intrinsically adiabatic nature of this theory of electronic energy transfer.

For two local transition dipoles μ_1 and μ_2 (“virtual oscillators”) associated with two atoms or molecules of the gas, the interaction W becomes $W_{12}(R) \propto \mu_1\mu_2/R^3$ and leads to the following expression for the energy-transfer cross section:

$$q = \int_0^\infty \left(1 + \frac{\sigma}{2\mu_1\mu_2} R^6\right)^{-1} \pi R dR \quad (5)$$

where R is the distance between the dipoles and σ is the energy mismatch between the adiabatic states of the donor and acceptor. In the Kallmann–London model, the appropriate energy levels become isoenergetic (a requirement necessary for the transfer to occur) thanks to the continuous kinetic energy distribution of particles in the gas phase. When $\sigma = 0$ we have a “sharp resonance” condition and the transfer is very efficient. The efficiency of transfer drops steeply as σ increases. While certain aspects of this model may have been incorrect (e.g., the adiabaticity of the process), it clearly played a crucial role in the development of the subsequent theories. One immediately recognizes the similarity with the density-matrix treatment of coherent excitation transfer, as well as with the Fermi “golden rule” if the interaction with one sharply defined acceptor eigenstate is replaced by an integration over a continuum of final states. The close resemblance between the final Eq. 5 and the Förster expression for the rate of singlet excitation transfer is also apparent.

In the following paragraphs we will briefly discuss the mechanisms of electronic excitation transfer most frequently encountered in molecular systems, and outline the formalism most commonly used to interpret energy-transfer data. More attention will be devoted to the exchange-mediated excitation transfer processes because of their particularly close relationship to charge transfer.

6.2 Singlet Energy Transfer

The first improved theory addressing the weakly coupled, or non-adiabatic electronic excitation transfer was the semiclassical vector model proposed by Förster [15]. It was further developed and refined by Levinson [16], Kasha [17], and others [18], who sometimes referred to it as the “molecular exciton theory”. Notably, this was the first successful attempt to link the rate of electronic excitation transfer with readily available experimental parameters, such as the absorption spectrum of the

acceptor and the fluorescence spectrum of the donor. In its original version, Förster's model, like the earlier theory of "quenching spheres" of Perrin [6], described the efficiency of excitation transfer in terms of the critical donor-acceptor separation R_0 :

$$R_0 = \left\{ \frac{9000(\ln 10)\kappa^2 \Phi_D J(\nu)}{128\pi^5 N_A n^4} \right\}^{1/6} \quad (6a)$$

and

$$k_{\text{SET}} = \frac{1}{\tau_0} \left(\frac{R_0}{R} \right)^6 \quad (6b)$$

where τ_0 is the intrinsic lifetime of the donor excited state, n is the solvent's refractive index, $J(\nu)$ is the spectral overlap integral which can be obtained by use of Levshin's "mirror image" rule [19], or by direct integration of the experimental spectra. The electronic coupling is contained in the "orientation factor", κ , which is determined by the magnitude and the mutual orientation of the local transition dipoles, μ_D and μ_A , of the donor and the acceptor. One of the most commonly used variants of the Förster expression for k_{SET} is given below

$$k_{\text{SET}} = \frac{8.79 \times 10^{-25}}{n^4} \cdot \frac{[\mu_D \cdot \mu_A - 3(\mu_D \cdot \mathbf{R})(\mu_A \cdot \mathbf{R})]^2}{R^6} \cdot \frac{\Phi_D}{\tau_D} \cdot \int_0^\infty F_D(\nu) A_A(\nu) d\nu \quad (7a)$$

with

$$\kappa = |\mu_D \cdot \mu_A - 3(\mu_D \cdot \mathbf{R})(\mu_A \cdot \mathbf{R})| = |\sin \vartheta \sin \varphi \cos \omega - 2 \cos \vartheta \cos \varphi| \quad (8)$$

where ϑ and φ are the angles between the respective transition dipoles and the vector \mathbf{R} connecting their centers, while ω is the dihedral angle defined by the three vectors μ_D , μ_A , and \mathbf{R} .

Perhaps the most distinguishing feature of bimolecular singlet energy transfer in solution is the fact that it can proceed at rates substantially faster than diffusion. When the Franck-Condon factors (i.e., the spectral overlap) are favorable and the transition dipoles of the donor and the acceptor are large, singlet energy transfer is much faster than the rate of donor-acceptor encounters. For example, it was observed early on that in the case of 1-chloroanthracene serving as the donor and perylene as the acceptor [20] k_{SET} exceeds $1 \times 10^{11} \text{ M}^{-1} \text{ s}^{-1}$ both in benzene and in liquid paraffin, even though the k_{diff} values for these two solvents are on the order of 10^{10} and $10^8 \text{ M}^{-1} \text{ s}^{-1}$, respectively. This is possible because the direct electro-

Figure 1. Theoretical dependence of the rates of various charge and excitation transfer processes on the donor–acceptor separation [21]. From top to bottom: **m**: conductivity of a metal; **d-d**: energy transfer by the electric dipole–electric dipole mechanism; **d-q**: energy transfer by the electric dipole–electric quadrupole mechanism; **CT**: superexchange-mediated charge transfer; **md-md**: energy transfer by magnetic dipole–magnetic dipole interaction; **TT**: superexchange-mediated triplet energy transfer. The curves were normalized to a common origin (this is not meant to imply that at minimum donor–acceptor separation all mechanisms lead to the same magnitude of coupling) and plotted versus distance in arbitrary units.

static coupling between the transition dipoles of the donor and the acceptor is a long-range interaction, which falls off relatively slowly with distance (Figure 1).

Electronic coupling

In 1953, Dexter presented a much broader theory of electronic energy transfer [22] and gave a detailed, quantitative description of the various electronic coupling mechanisms. He pointed out that the donor–acceptor coupling is formally described by the Coulomb and exchange integrals between the localized wave functions of the relevant electronic ground and excited states. Dexter’s treatment includes the Förster model as a special-case excitation transfer involving spin-allowed transitions of the donor and the acceptor. The electrostatic Coulomb interaction can be conveniently represented as a Taylor expansion of interactions between electrical multipoles centered on the donor and the acceptor (Eq. 9). Thus, Förster’s theory corresponds to truncating the multipole expansion after the first dipole–dipole term:

$$\begin{aligned}
 V_{\text{DA}} = & \frac{e^2}{\epsilon R^3} \cdot \left\{ \frac{\mathbf{r}_D \cdot \mathbf{r}_A - 3(\mathbf{r}_D \cdot \mathbf{R})(\mathbf{r}_A \cdot \mathbf{R})}{R^2} \right\} + \text{dipole-dipole} \\
 & + \frac{3e^2}{2\epsilon R^4} \cdot \left\{ \sum_{k=1}^3 \frac{R_i}{R} r_{Di} r_{Ai}^2 \left(-3 + \frac{5R_i^2}{R^2} \right) \right. \\
 & \quad \left. + 10 \frac{XYZ}{R^3} (x_A y_A z_D + x_A z_A y_D + y_A z_A x_D) + \dots \right\} + \dots \text{dipole-quadrupole} \\
 & - \int \phi'_D(\mathbf{r}_1) \phi_A(\mathbf{r}_2) \frac{1}{r_{12}} \phi'_A(\mathbf{r}_1) \phi_D(\mathbf{r}_2) d\tau \quad \text{exchange}
 \end{aligned} \tag{9}$$

If the local transitions of both chromophores are strongly allowed, the dipole-dipole interaction indeed dominates the expansion, and it has been shown in countless experiments that the approximation is satisfactory. Since it corresponds to the interaction between two point dipoles, the donor-acceptor center-to-center distance R (defined as the distance between the centers of mass of the local charge distributions) should be considerably larger than the length of either dipole. At short distances, the point dipole approximation should break down and either inclusion of higher-order multipoles, or explicit summation of interactions between charges assigned to individual atoms (point monopoles) of the donor and the acceptor may be necessary. Similarly, at small donor-acceptor separations, the exchange coupling (see Figure 2 further on) should also contribute significantly to singlet energy transfer. The departure from the ideal $1/R^6$ distance dependence of the rate (Figure 1) is usually taken to indicate the presence of other coupling mechanisms. However, in nearly all studied cases, including systems with closely coupled donors and acceptors, the rate of singlet energy transfer can be fully accounted for by the dipole-dipole interaction and there are only a few examples of model systems in which it was possible to achieve an appreciable contribution from the higher multipole or exchange terms [23]. Most likely, there are two main reasons for this behavior: Firstly, in many cases of flexible model compounds, the donor-acceptor separation, and even more so, the mutual orientation of the transition dipoles, are not known with a precision sufficient to make a strong case for the presence of other coupling mechanisms. More fundamentally, as was pointed out by Scholes and Ghiggino [24], the different contributions to the coupling, including the short-distance penetration term not discussed by Dexter, can carry opposite signs, thus leading to constructive and destructive interference effects somewhat analogous to the pathway interference effects familiar from electron transfer studies [25].

In general, each interaction in Eq. 9 has its own distinct orientation dependence. Nevertheless, it is possible to construct rigid donor-acceptor systems of such symmetry that all terms of the multipole expansion, as well as the exchange coupling, are rigorously equal to zero. Levy, Piotrowiak, and collaborators used spirobifluorenes (D_{2d} point group) to demonstrate that such perfect symmetry cancellation of the donor-acceptor coupling can indeed be obtained; however, it can be observed only in degenerate, or nearly degenerate bichromophoric molecules at the

bottom of the respective vibrational manifolds [26]. Populating vibrationally excited states of the donor (excess energy $\geq 600 \text{ cm}^{-1}$), or introducing a large donor–acceptor energy gap ($\Delta E \geq 1000 \text{ cm}^{-1}$) leads to efficient vibronic coupling and very rapid energy transfer ($k_{\text{SET}} \approx 1 \times 10^{12} \text{ s}^{-1}$) [27]. It is likely that vibronic mixing with higher, essentially localized excited states plays an important role in providing the interchromophore coupling. On the basis of this work, it can be generalized that vibronic coupling effects are likely to be of importance for most donor–acceptor systems used in excitation and charge-transfer studies, since the employed free-energy gaps are typically much larger than a few hundred wavenumbers [28].

Mediated singlet excitation transfer

For reasons outlined above, the donor–acceptor coupling in singlet energy transfer is usually viewed as a direct electrostatic interaction between the localized transition dipoles. The only role of the intervening medium is to screen this interaction depending on the value of ϵ^2_{∞} or n^4 . This overly simplistic view has been challenged by several groups, particularly by Paddon-Row, Scholes, and Ghiggino [23, 29], who studied, in detail, various coupling contributions to the singlet energy transfer in a well-characterized rigidly linked bichromophore. It was found that the “through-bond” exchange coupling was the dominant mechanism, followed by the direct dipole–dipole interaction, and by the “relayed Coulomb coupling”, that is, a mechanism of donor–acceptor interaction which involves the virtual excitations of the bridging moiety. This sequential donor \leftrightarrow bridge \leftrightarrow acceptor interaction is essentially a variant of the original concept of superexchange, only applied to a different type of excitation and, hence, employing a different basis set. The resulting formula for relayed Coulombic electronic coupling does, indeed, closely resemble the classic McConnell perturbation theory expression [30] for superexchange-mediated electron transfer. Treating the bridge as a single excitable unit, one obtains, within the dipole–dipole approximation that

$$V_{\text{relay}}^{\text{dd}} \approx \frac{V_{\text{donor-bridge}}^{\text{dd}} V_{\text{bridge-acceptor}}^{\text{dd}}}{\Delta E_{\text{average}}} \quad (10)$$

where $\Delta E_{\text{average}}$ is the average energy gap between the excited state of the bridge and the excited states of the donor and the acceptor, and $V_{\text{donor-bridge}}$ and $V_{\text{bridge-acceptor}}$ are expressed in terms of the standard dipole–dipole coupling. In the case of the frequently employed saturated hydrocarbon bridges, the difference between the $\Delta E_{\text{donor-bridge}}$ and $\Delta E_{\text{bridge-acceptor}}$ is negligibly small, since the $\sigma \leftrightarrow \sigma^*$ transition of the bridge lies approximately 3 eV ($24,000 \text{ cm}^{-1}$) or more above the S_1 states of typical chromophores. Interestingly, the sign of the Coulombic relay contribution was the opposite of those of exchange and dipole–dipole interactions. The importance of mixing of the orthogonally polarized local transitions of the donor and/or acceptor was also investigated. It was found that this “pre-mixing” can increase the overall coupling by more than an order of magnitude.

The most convincing demonstration of the importance of the “Coulombic relay mechanism,” or a bridge-exciton-mediated singlet energy transfer, comes from the

recent work of Albinsson et al., who investigated an elegant series of porphyrin-based bichromophores linked by bridges of equal length but with widely differing excited-state energies [39]. The $\Delta E_{\text{donor-bridge}}$ was varied over the range from 4000 to 18000 cm^{-1} and a very good linear correlation between the measured singlet energy transfer rates and $(1/\Delta E_{\text{donor-bridge}})^2$ was obtained. Importantly, the bridge-chromophore energy gap was always kept well above the average thermal energy, thus avoiding the possibility of trivial stepwise energy transfer (i.e., exciton hopping or energy migration). It is possible that the through-bond exchange coupling also makes a significant contribution in these systems.

Spectral overlap and the Franck–Condon density of states

The possibility of expressing the Franck–Condon density of states in terms of the experimentally measurable spectral overlap integral is a unique and valuable feature of the Förster theory and singlet energy transfer. The resulting density of states is free of approximations introduced in the classical or semiclassical theoretical expressions for the Franck–Condon factors used in electron-transfer studies. All familiar aspects of the Marcus and Marcus–Jortner treatments of the Franck–Condon factors, including the existence of the “inverted region” at large donor–acceptor energy gaps, are inherently present in the spectral overlap integral. This is more readily appreciated when one treats the emission band of the donor and the absorption band of the acceptor as symmetric Gaussian functions whose widths are determined by the respective Stokes parameters S_D and S_A . In this case, the spectral overlap integral can be expressed in closed form, and the expression for k_{SET} becomes virtually identical with the Marcus equation, with the sum of Stokes shifts of the donor and acceptor, $S_D + S_A$ taking the place of the reorganization energy λ :

$$k_{\text{SET}} = V_{\text{DA}}^2 \cdot \sqrt{\frac{1}{4k_B T(S_D + S_A)}} \cdot \exp \left[-\frac{[\Delta E_{\text{DA}} - (S_D + S_A)]^2}{4k_B T(S_D + S_A)} \right] \quad (11)$$

Unlike in the case of electron and triplet energy transfer, it seems that there has not been much interest in mapping out the driving-force dependence of singlet energy transfer in the highly exoergic range. The author is aware of only a few reported cases of the “inverted region” or “gap law” behavior [32].

Coherent energy transfer

Finally, we should mention the possibility of coherent excitation transfer when the donor–acceptor interaction is strong, but the coupling of the system to the thermal bath is weak. The resulting two-level weakly damped system lends itself to the time-dependent density-matrix approach [33], which is essentially identical to the familiar spin-1/2 treatment in magnetic resonance. Under certain circumstances, coherence effects can be important for singlet energy transfer, because the donor states are populated instantaneously by direct photoexcitation. With a sufficient band width of the excitation source (e.g., ultrashort femtosecond pulses), quantum superposition states can be prepared in a coherent fashion even in condensed media at room

temperature, and a broad array of polarization transfer and coherence transfer phenomena can be studied. In the case of spin-forbidden $S_0 \rightarrow T_1$ transitions, the donor T_1 state is populated by intersystem crossing from the S_1 state and any coherence of the original state is usually lost before the excitation transfer can take place. Therefore, coherence effects are very unlikely in triplet energy transfer at ambient conditions.

6.3 Triplet Energy Transfer

Förster theory and its variants have been very successful for treating energy transfer between donors and acceptors with strong allowed electronic transitions. However, this approach is not applicable to electronic energy transfer leading to spin multiplicity changes of the donor and/or acceptor unit. Such processes abound especially in organic molecular systems, in which the spin multiplicity is always well defined and the spin-orbit coupling relatively weak. However, it was the problem of excitation transfer ("sensitized luminescence") in inorganic solids that prompted further theoretical development in this area. Dexter demonstrated that triplet energy transfer (or, more generally, any electronic excitation transfer involving spin-forbidden local transitions) can proceed owing to the exchange coupling between the donor and the acceptor [22, 34]. As will be shown below, the exchange interaction can be viewed as a two-electron two-orbital analog of the one-electron two-orbital resonance integral. As a result, triplet excitation transfer is mechanistically much more closely related to charge-transfer processes than to spin-allowed singlet energy transfer.

Electronic coupling

To describe electronic energy transfer involving spin-forbidden vertical transitions, one must write the wave functions of the initial and the final state so that they explicitly contain the spin functions:

$$\Psi_I = \varphi'_D(\mathbf{r}_1)\chi'_D(\sigma_1)\varphi_A(\mathbf{r}_2)\chi_A(\sigma_2) - \varphi'_D(\mathbf{r}_2)\chi'_D(\sigma_2)\varphi_A(\mathbf{r}_1)\chi_A(\sigma_1) \quad (12a)$$

$$\Psi_F = \varphi_D(\mathbf{r}_1)\chi_D(\sigma_1)\varphi'_A(\mathbf{r}_2)\chi'_A(\sigma_2) - \varphi_D(\mathbf{r}_2)\chi_D(\sigma_2)\varphi'_A(\mathbf{r}_1)\chi'_A(\sigma_1) \quad (12b)$$

where φ_i is the spatial part of the wave function and χ_i is the spin part of the wave function. Now we can explicitly write out the matrix elements of the perturbation Hamiltonian H_1 , at the same time separating the spatial and spin integrals (the Hamiltonian $H_1 = e^2/r_{12}$ does not operate on spin functions and, therefore, such factoring out is possible):

$$\begin{aligned} V_{DA} &= \langle H_1 \rangle \\ &= \langle \varphi'_D(\mathbf{r}_1)\varphi_A(\mathbf{r}_2) | H_1 | \varphi_D(\mathbf{r}_1)\varphi'_A(\mathbf{r}_2) \rangle \times \langle \chi'_D(\sigma_1)\chi_A(\sigma_2) | \chi_D(\sigma_1)\chi'_A(\sigma_2) \rangle \\ &\quad - \langle \varphi'_D(\mathbf{r}_1)\varphi_A(\mathbf{r}_2) | H_1 | \varphi'_A(\mathbf{r}_1)\varphi_D(\mathbf{r}_2) \rangle \times \langle \chi'_D(\sigma_1)\chi_A(\sigma_2) | \chi'_A(\sigma_1)\chi_D(\sigma_2) \rangle \end{aligned} \quad (13)$$

The first term in the above expression is the Coulomb-interaction term, which vanishes, unless

$$\chi'_{\text{D}} = \chi_{\text{D}} \quad \text{and} \quad \chi_{\text{A}} = \chi'_{\text{A}}$$

that is, the Coulomb interaction allows only transitions which preserve the spin multiplicity of the donor and the acceptor units; it does, however, allow electronic-energy transfer between donor and acceptor of different spin multiplicity (this is of minor importance for organic systems, since there are very few stable compounds with ground-state spin other than 0, and the $^3\Sigma_{\text{g}}^-$ to $^3\Sigma_{\text{u}}^-$ transition of the ubiquitous molecular oxygen is symmetry-forbidden).

The second term in the above expression is the exchange integral, for which the following selection rules apply:

$$\chi'_{\text{D}} = \chi'_{\text{A}} \quad \text{and} \quad \chi_{\text{D}} = \chi_{\text{A}}$$

that is, χ does not have to be equal to χ' , so the spin functions on both chromophores can change simultaneously. Therefore, for $\chi'_{\text{D}} = \chi'_{\text{A}}$, $\chi_{\text{D}} = \chi_{\text{A}}$ and $\chi'_{\text{D}} \neq \chi_{\text{D}}$, $\chi_{\text{A}} \neq \chi'_{\text{A}}$ the expression for the donor-acceptor interaction simplifies to

$$V_{\text{DA}} = \langle H_1 \rangle = -\langle \varphi'_{\text{D}}(\mathbf{r}_1) \varphi_{\text{A}}(\mathbf{r}_2) | H_1 | \varphi'_{\text{A}}(\mathbf{r}_1) \varphi_{\text{D}}(\mathbf{r}_2) \rangle \quad (14)$$

The exchange integral is, in principle, a purely quantum-mechanical result of the antisymmetrization of the electronic wave function and, therefore, does not possess an obvious classical analogue. One may try to visualize the exchange interaction by creating two virtual charge distributions Q' and Q given by $Q'(\mathbf{r}_1) = \varphi'_{\text{D}}(\mathbf{r}_1) \varphi'_{\text{A}}(\mathbf{r}_1)$ and $Q(\mathbf{r}_2) = \varphi_{\text{D}}(\mathbf{r}_2) \varphi_{\text{A}}(\mathbf{r}_2)$ and rewriting Eq. 14 accordingly. However, more insight can be gained by rewriting the spatial portions of the excited and ground state wave functions of the donor and the acceptor in terms of the products of the corresponding localized HOMO and LUMO orbitals. In this zero-order orbital approximation, the spatial wave function of the lowest excited state (either triplet or singlet) becomes $\varphi' = \varphi^{\text{LUMO}} \varphi^{\text{HOMO}}$, and for the ground state $\varphi = \varphi^{\text{HOMO}} \varphi^{\text{HOMO}}$. In this basis set, Eq. 14 transforms into

$$|V_{\text{DA}}| = |\langle \varphi_{\text{D}}^{\text{LUMO}}(1) \varphi_{\text{A}}^{\text{HOMO}}(2) | H_1 | \varphi_{\text{A}}^{\text{LUMO}}(1) \varphi_{\text{D}}^{\text{HOMO}}(2) \rangle| \quad (15)$$

which explicitly shows that triplet energy transfer can be described as a double electron exchange between the HOMO and LUMO orbitals of the donor and the acceptor. This concept is frequently represented graphically, as shown in Figure 2. Naturally, if the HOMO orbitals are replaced by the valence band of a semiconductor, and the LUMO orbitals by the corresponding conduction band, one obtains the commonly accepted mechanism of triplet exciton migration in semiconductors. The same model can be used to explain triplet exciton mobility in molecular solids [35].

The simplification of Eq. 15 can be taken even further. Since the Hamiltonian $H_1 = 1/r_{12}$ varies very slowly with distance compared to the exponential decay of

Figure 2. Schematic representation of electron, hole, and triplet energy transfer between the localized HOMO and LUMO orbitals of the donor and the acceptor. Note that the above diagram also applies to the exchange-mediated singlet excitation transfer if the spin of the electron in the LUMO orbital is reversed.

electronic wave functions, it can be, perhaps somewhat daringly, postulated that $1/r_{12}$ can be approximated by its average value, which, in turn, for weakly interacting systems will be approximately equal to the inverse of the center-to-center donor-acceptor distance, $\langle 1/r_{12} \rangle \approx 1/r_{DA} = \text{const.}$ As a result, one obtains

$$\begin{aligned}
 V_{DA}^{TT} &\approx \text{const.} \cdot \langle \phi_D^{\text{LUMO}}(1) \phi_A^{\text{HOMO}}(2) | \phi_A^{\text{LUMO}}(1) \phi_D^{\text{HOMO}}(2) \rangle \\
 &= \text{const.} \cdot \langle \phi_D^{\text{LUMO}}(1) | \phi_A^{\text{LUMO}}(1) \rangle \langle \phi_A^{\text{HOMO}}(2) | \phi_D^{\text{HOMO}}(2) \rangle \\
 &\approx \text{const}' \cdot V_{DA}^{\text{ET}} \cdot V_{DA}^{\text{HT}}
 \end{aligned} \tag{16}$$

In the approximate expression above, the two-electron two-orbital exchange integral is effectively replaced by the product of the overlap integrals between the LUMO and HOMO orbitals of the donor and the acceptor. Within the framework of the same assumption ($1/r$ varying slowly compared to the decay of the wave function), these overlap integrals can be viewed as approximations of the resonance integrals corresponding to electron transfer and hole transfer, respectively. As a consequence, the electronic coupling element responsible for triplet energy transfer becomes proportional to the product of the electronic coupling for the electron and hole transfer processes, $V^{TT} \propto V^{\text{ET}} \cdot V^{\text{HT}}$, and since the transfer rates are proportional to $|V|^2$, it can be also stated that $k^{TT} \propto k^{\text{ET}} \cdot k^{\text{HT}}$.

Furthermore, since the electronic coupling, and the rates of all three processes, fall off exponentially with distance, with characteristic slopes of β^- , β^+ , and β^{TT} :

$$\begin{aligned}
 V^{\text{ET}} &= V_0^{\text{ET}} \cdot \exp\{-[\beta^-(R_{DA} - R_0)/2]\} \\
 k^{\text{ET}} &= k_0^{\text{ET}} \cdot \exp\{-[\beta^-(R_{DA} - R_0)]\}
 \end{aligned} \tag{17a}$$

$$V^{\text{HT}} = V_0^{\text{HT}} \cdot \exp\{-[\beta^+(R_{\text{DA}} - R_0)/2]\}$$

$$k^{\text{HT}} = k_0^{\text{HT}} \cdot \exp\{-[\beta^+(R_{\text{DA}} - R_0)]\} \quad (17b)$$

$$V^{\text{TT}} = V_0^{\text{TT}} \cdot \exp\{-[\beta^{\text{TT}}(R_{\text{DA}} - R_0)/2]\}$$

$$k^{\text{TT}} = k_0^{\text{TT}} \cdot \exp\{-[\beta^{\text{TT}}(R_{\text{DA}} - R_0)]\} \quad (17c)$$

Hence it can be written that

$$V^{\text{TT}} \propto V_0^{\text{ET}} \cdot V_0^{\text{HT}} \cdot \exp\{-[\beta^-(R_{\text{DA}} - R_0)/2]\} \cdot \exp\{-[\beta^+(R_{\text{DA}} - R_0)/2]\}$$

$$= V_0^{\text{ET}} \cdot V_0^{\text{HT}} \cdot \exp\{-[(\beta^- + \beta^+)(R_{\text{DA}} - R_0)/2]\} \quad (18)$$

from which it follows directly that $\beta^{\text{TT}} = \beta^- + \beta^+$ (V_0 and k_0 correspond to the minimum donor-acceptor separation, $R = R_0$, for example, one σ -bond in a bridged system, or van der Waals contact in a glass or liquid solution).

The validity of these simple approximations in weakly coupled bridged donor-acceptor systems was tested experimentally on a carefully designed family of homologous donor-acceptor compounds [36]. The distance dependence of intramolecular triplet energy transfer was determined for the first time and compared with the corresponding electron and hole transfer distance dependencies [37]. Identical saturated hydrocarbon bridge units (cyclohexane and trans-decalin) and stereochemical attachments were used in all three series of experiments (electron [38], hole [39], and triplet [36] energy transfer). Biphenyl served as the donor and naphthalene as the acceptor in the pulse radiolysis measurements of electron and hole transfer rates [40]. For energy-transfer studies biphenyl was replaced by benzophenone as the triplet donor; however, naphthalene was retained as the acceptor. The variation of the electronic structure of the model compounds was therefore, as far as possible, kept to a minimum. The resulting correlation of transfer rates is shown in Figure 3.

It should be emphasized that the linearity of the plot in Figure 3 is merely a consequence of the rates of both charge transfer and triplet excitation transfer being exponentially distance dependent. It is the slope of the resulting line that contains the information about the relationship between the respective electronic coupling elements. In Figure 3, the slope is, within experimental error, equal to one, confirming that, indeed, $\beta^{\text{TT}} = \beta^- + \beta^+$.

A satisfactory agreement between the distance dependence of the rate of triplet energy transfer and the rate of electron transfer alone could also be obtained in these model systems, with $\beta^{\text{TT}} \approx 2\beta^{\text{ET}}$, showing that, for a comparable bridge, the rate of triplet energy transfer falls off twice as rapidly with increasing donor-acceptor separation as with electron transfer (Figure 4) [42, 43]. It is remarkable that this correlation is maintained for triplet transfer rates spanning five orders of magnitude. This behavior can be attributed to the approximately symmetric displacement of the HOMO and LUMO orbitals of aromatic donors and acceptors, which leads to approximately equal values of β^+ and β^- .

It is also worthwhile to point out that the correlation plots in Figures 3 and 4 contain systems with all possible stereochemical attachments of the donor and acceptor to the bridge (equatorial-equatorial, equatorial-axial and axial-equatorial).

Figure 3. Correlation between the experimentally measured rates of triplet energy transfer and the scaled product of the appropriate electron and hole transfer rates [41]. The straight line indicates the slope of unity which corresponds to $\beta^{TT} = \beta^- + \beta^+$.

Figure 4. Correlation between the experimentally measured rates of triplet energy transfer and the electron transfer rates in analogous model compounds [41]. The fitted line indicates that $\beta^{TT} = 2.18 \cdot \beta^-$, nearly in perfect agreement with the simplified theory.

The stereochemistry of the attachment to the bridge primarily affects the corresponding V_0 , which determines only the intercept at $R = R_0$, and has a negligible influence on the slope of the distance dependence. The differences in V_0 can be large, so that different sets of stereoisomers must be analyzed separately. However, in all three processes studied (electron, hole, and triplet transfer) the dependence of V_0 on the donor–acceptor stereochemistry was the same, with the equatorial–equatorial isomers always giving the highest V_0 , and leading to a nearly constant value of $V_0^{\text{TT}}/(V_0^{\text{ET}} \cdot V_0^{\text{HT}})$, regardless of the attachment pattern. This self-cancellation effect further confirms the validity of the approximate picture.

The model compounds of Closs, Miller, and Piotrowiak were subsequently treated computationally by Morokuma and coworkers [44]. The results of their *ab initio* calculations agreed with the experimental observations and showed that the dependence of V^{TT} on the donor–acceptor separation and on the stereochemistry of the attachment to the bridge closely tracks that of the product of V^{ET} and V^{HT} .

The described relationship between charge transfer and triplet energy transfer processes is expected to be general for most donor–acceptor systems, provided that a few important criteria are met: (1) The wave functions of the excited state and the radical ions of the donors and acceptors must be well represented by the zero-order HOMO–LUMO approximations. As a consequence, the correlation is likely to break down in the presence of strong configuration interaction. (2) All involved states, that is, the reduced, oxidized, and triplet states of the donor and acceptor, must be well below the appropriate virtual states of the bridging unit, thus satisfying the conditions of weak coupling propagating by the superexchange mechanism. Strongly coupled systems, for example, those involving conjugated bridges are likely to depart from the linear correlation. (3) The spin states of all components must be well defined (this is frequently not the case if transition metal complexes serve as the donor and/or acceptor) [45].

Franck–Condon factors and the reorganization energy

The rate of triplet energy transfer in the original Dexter formulation is given by

$$k_{\text{TT}} = \frac{2\pi}{\hbar} |V_{\text{DA}}|^2 \cdot \int f_{\text{D}}(E) F_{\text{A}}(E) dE \quad (19)$$

where f_{D} is the normalized emission spectrum of the donor and F_{A} is the normalized absorption spectrum of the acceptor. In the case of triplet energy transfer they correspond to the phosphorescence and the $S_0 \rightarrow T_1$ absorption spectra, respectively. Unfortunately especially the latter, can frequently not be readily measured in organic molecules. Therefore, expressing the Franck–Condon density of states in terms of spectral overlap, which is so convenient in the analysis of singlet energy transfer processes, is generally impractical for triplet transfer. Instead, the semi-classical Marcus–Jortner formula [46] used in most electron-transfer studies can be applied here without any modification. Thus, the expression for the rate of triplet excitation transfer becomes

$$k_{\text{TT}} = \left(\frac{\pi}{\hbar^2 \lambda_{\text{s}} k_{\text{B}} T} \right)^{1/2} \cdot |V^{\text{TT}}|^2 \cdot \sum_{n=0}^{\infty} e^{-S} \cdot \frac{S^n}{n!} \cdot e^{-(\Delta G_0 + \lambda_{\text{s}} + n\hbar\nu)^2 / (4\lambda_{\text{s}} k_{\text{B}} T)} \quad (20)$$

where $S = \lambda_v/h\nu$, λ_s and λ_v are the low-frequency (classical) and high-frequency (quantized) contributions to the nuclear reorganization energy, ν is the average frequency of the vibrational mode coupled to the electronic coordinate, n is the vibrational quantum number of the final state, and all other symbols have their usual meaning.

It has been experimentally demonstrated by several groups using covalently linked organic [47] and organometallic [48] model compounds, as well as freely diffusing [49] and incarcerated [50, 51] donors and acceptors, that the Marcus–Jortner equation adequately describes the driving-force dependence of triplet energy-transfer rates, and that as for electron transfer, the highest rates occur when the Franck–Condon factors are optimized, approximately at $-\Delta G^\circ = \lambda_{\text{total}}$. When the optimum free energy of reaction is exceeded, one enters the “inverted region” and the rates begin to diminish (Figure 5).

Figure 5. Free-energy dependence of triplet energy transfer from a biacetyl donor trapped within a hemicarcerand cage to several rigid aromatic acceptors in solution. Note that the curve is much narrower, and that the “inverted region” is reached at a much lower value of ΔG° than is typically observed in electron-transfer systems. The oscillations in the calculated line are artifacts of the single high frequency mode approximation (from the work of Deshayes, Piotrowiak, et al. [52]).

While the overall appearance of the above equation is the same for charge and excitation transfer, the relative importance of various terms can be very different. In the case of electron transfer, the overall reorganization energy is dominated by the solvent contribution λ_s , which, according to the simplest continuum model of solvation, depends on the effective radii of the donor and the acceptor, the separation between them, and the dielectric constant of the medium. In polar solvents, the magnitude of the solvent-reorganization energy can readily exceed 1 eV (ca. 23 kcal/mol). Consequently, a correction for the large variation in λ_s , usually based on the Born expression, must be included in the analysis electron-transfer data. The variations in the magnitude of λ_v , which is typically much smaller (typically 3–4 kcal/mol for each of the reactants) are usually ignored without much detriment to agreement with the experimental results.

The partitioning between the internal and external components of the reorganization energy in triplet transfer is the opposite of that found for electron transfer. Triplet energy transfer does not involve a major redistribution of charges between the donor and the acceptor. Indeed, often even the dipole moments of the individual moieties, and of the entire assembly, remain unchanged (e.g., among the commonly used donors and acceptors this applies to biacetyl, naphthalene, anthracene, and pyrene). Therefore, the corresponding solvent-reorganization energy is very small, typically less than 0.1 eV. As a result, λ_v is the leading component of the overall reorganization energy in triplet transfer, and the transfer rates become extremely sensitive to this parameter. The dominance of λ_v is further amplified by the fact that the absolute magnitude of the internal reorganization energy is usually considerably larger for triplet transfer than it is for electron transfer, and in some cases, primarily the olefins, it can exceed 1 eV (Table 1).

While at first it might seem counterintuitive, this effect is readily explained in terms of the simplest zero-order orbital picture of the electron and electronic excitation transfer processes. Triplet transfer to and from a typical closed-shell organic molecule involves a change in occupancy of both the HOMO and LUMO orbitals of the donor and the acceptor. For an olefinic or aromatic donor or acceptor, this can be represented as $\pi^1\pi^{*1} \rightarrow \pi^2\pi^{*0}$ (donor) and $\pi^2\pi^{*0} \rightarrow \pi^1\pi^{*1}$ (acceptor). This results in the overall bond order being changed by one. The analogous reduction and oxidation processes (either thermal or photoinduced) involve only one occupancy change, $\pi^2\pi^{*0} \rightarrow \pi^2\pi^{*1}$ (reduction) and $\pi^2\pi^{*0} \rightarrow \pi^1\pi^{*0}$ (oxidation), with the corresponding bond order change of 1/2. Table 1 contains internal reorganization energies calculated at the AM1 semi-empirical level (except where noted) for a selection of commonly used donors and acceptors [53]. While the individual values of λ_v obtained at such a low level of computation should be taken very cautiously, the overall trends are clearly visible, with the triplet reorganization energy usually being at least twice as large as that associated with the formation of the corresponding radical anion or the radical cation. The notable exceptions include molecular oxygen and biacetyl, both of which exhibit unusually low triplet reorganization energies.

The importance of structural relaxation in triplet energy transfer was recognized some time ago by Balzani [54, 55]. The dependence of triplet energy transfer rates on the magnitude of internal reorganization energy was investigated experimentally by Deshayes, Piotrowiak, and coworkers [52]. Acceptors with internal reorganiza-

tion energies ranging from nearly zero to more than 1 eV were investigated. The same donor, biacetyl encapsulated in a hemicarcerand cage, was employed in all cases. It was found that quenchers with nearly identical triplet energies can lead to transfer rates differing by almost three-orders of magnitude as a result of large differences in their internal reorganization energies (Figure 6). It was concluded that a meaningful ΔG° dependence can be obtained only if the acceptors are separated into groups with similar internal reorganization energies: (a) Rigid aromatics with small geometry changes and modest internal reorganization energies (Figure 5); (b) Olefins exhibiting a large-amplitude internal relaxation and correspondingly large reorganization energies. The olefins provide an interesting example, which shows that the terms “internal” and “high-frequency” reorganization energy are not always synonymous. Not surprisingly, the major fraction of reorganization energy in an olefin is associated with the twisting of the formally double bond. However, the olefin twisting motion on the product side usually corresponds to vibrational frequencies lower than kT and, therefore, contributes to the low-frequency λ_s , rather than the high-frequency λ_v [47, 56, 57]. The study also demonstrated that molecular oxygen, with its negligibly small internal reorganization energy, is a

Figure 6. The driving-force (in eV) dependence of non-radiative transfer rates (in arbitrary units) predicted by the Marcus–Jortner equation for total reorganization energies of 0.1, 0.3, 0.5, 1.0, and 1.5 eV. Various ratios of λ_s and λ_v were used for the individual traces.

unique triplet energy acceptor, excelling at quenching low-energy triplets; however, because of very unfavorable Franck–Condon factors, it is not particularly efficient in quenching high-energy triplets with small reorganization energies [58].

6.4 Summary

Almost exactly 50 years ago, James Franck remarked: “Migration of excitation energy between molecules or inside a molecule from one of its groups to another is observed under many different conditions. The transferred excitation energy may be used just as the directly absorbed light energy for the promotion of chemical process, or it may be dissipated into heat. The most remarkable facts are that the excitation energy under suitable conditions can be transferred with a high yield over

distances of $\sim 50\text{--}100\text{ \AA}$ and that molecules or molecular groups which do not possess the quality to fluoresce still are able to transfer their excitation energy to energy acceptors which may not be in contact with them. There is no doubt that every example of transfer of electronic excitation energy observed so far can be understood either by an electron migration, or by exciton migration, or by the process of sensitized fluorescence, but in many cases uncertainty exists as to whether one of these three processes is solely responsible for a particular phenomenon and, if so, which one it is . . . Especially, interpretations of energy transfer by and in substances of biological importance are often based on doubtful hypotheses.” [59].

It is rather noteworthy that Franck wrote the above paragraph well before the seminal contributions of Dexter [22], Terenin, and Ermolaev [8], or Marcus [46a], Jortner [46b], Miller [13], and Closs [13b]. Most impressively, essentially all of his comments were proven correct. While we have certainly advanced beyond “doubtful hypotheses”, electronic excitation transfer in biological systems continues to be the most fascinating and challenging problem. The recent X-ray determination of the intriguing structures of the LH1 and LH2 antenna complex [60] brought a new wave of interest among theorists [61] and experimentalists [62], similar to that which followed the solution of the bacterial photoreaction center some time ago [63]. The spectroscopic behavior of the antenna arrays could not be explained in terms of the standard Förster theory and led to the development of the distributed transition dipole approach [61], which is likely to be helpful in the treatment of other complex nonbiological multichromophoric systems. Charge and excitation transfer processes mediated by non-carbon based bridges are only beginning to receive well-deserved attention, with the few available results seemingly challenging the common intuition [64]. There is also a renewed interest in charge- and energy-transfer processes in strongly coupled adiabatic systems (mixed-valence compounds and J-aggregates). Strongly coupled multichromophoric systems in which the distinction between charge and energy transfer becomes arbitrary will be particularly interesting. Among the little explored mechanisms of donor–acceptor coupling, the spin–orbit interaction, which is often viewed only as a wasteful sink accelerating the non-radiative decay to the ground state, should be studied in more detail. Indeed, artificially enhanced spin–orbit coupling has been used recently in the development of organic light emitting diodes (LEDs) with record efficiencies, nearly reaching the theoretical limit [65]. Among the more exotic applications of electronic excitation transfer one could envision the use of a sequence of weakly endoergic singlet energy transfers to increase the efficacy of laser cooling processes [66].

40. Pulse radiolysis in chlorinated solvents leads to the formation of radical cations of almost all organic compounds including aryls. In most non-halogenated solvents, pulse radiolysis results in the formation of solvated electrons and radical anions of the solute. Therefore, depending on the selected solvent, the same donor-acceptor system could be used for the electron and hole transfer studies.

45. The large spin-orbit coupling in chromophores bearing heavy atoms introduces mixing of states with different spin multiplicities. As a result, the spin of the donor and the acceptor can become ill-defined on the timescale of excitation transfer. In these cases, the sharp distinction between exchange-mediated triplet transfer versus Coulomb-mediated singlet transfer is no longer meaningful. This is of particular concern in transition metal complexes. For example, the formal triplet charge-transfer state of Os^{II} complexes has a considerable singlet character. Therefore, the conclusions regarding triplet and electron-transfer rates drawn in R. E. Holmlin, R. T. Tong, J. K. Barton, *J. Am. Chem. Soc.* **1998**, *120*, 9724 are most likely incorrect.

53. Experimental values of triplet reorganization energies are, in general, difficult to obtain. The Franck-Condon triplet energies are most often derived from the extremely weak $T_1 \leftarrow S_0$ absorption induced either by a solvent containing heavy atoms or by complexation with O₂. Values obtained for molecules with $T_1 \leftarrow S_0$ spectra without a clearly defined 0-0 peak carry a large margin of error. The energies of the fully relaxed triplet states of olefins are usually obtained either from equilibria measured with species whose triplet energies are well established, or by photoacoustic experiments. These approaches tend to be less reliable than simple phosphorescence measurements, especially in the case of short-lived triplets. Some values can

- be found in: (a) A. A. Gorman, I. R. Gould, I. Hamblett, *J. Am. Chem. Soc.* **1981**, *103*, 4553; (b) A. A. Gorman, I. Hamblett, R. J. Harrison, *J. Am. Chem. Soc.* **1984**, *106*, 6952; (c) R. Caldwell, A. D. Strickland, *J. Phys. Chem.* **1993**, *97*, 13394.
54. V. Balzani, F. Bolletta, F. Scandola, *J. Am. Chem. Soc.* **1980**, *102*, 2105.
55. The early discussion of the role of nuclear reorganization in energy transfer, especially among classical photochemists, centered on the concept of "nonvertical excitation transfer". While many of the conclusions fully agree with the spirit of the Marcus–Jortner approach, the term itself is rather unfortunate as it suggests that the process may be violating the Franck–Condon principle and the Born–Oppenheimer approximation.
56. A similar situation occurs when biphenyl is used as triplet acceptor, see D. Zhang, G. L. Closs, D. D. Chung, J. R. Norris, *J. Am. Chem. Soc.* **1993**, *115*, 3670.
57. Where there is a significant change in the frequency of the relevant mode (or modes) upon crossing from the reactant to the product side, but the mode remains strongly quantized, the Franck–Condon factors can be obtained with the more general expression given by W. Siebrand, *J. Phys. Chem.* **1967**, *46*, 440. This still corresponds to a single-mode approximation, but with the final frequency ν_F being different from the initial one, ν_I . The summation over all vibrational levels n of the final state coupled to the lowest vibrational level of the initial state yields

$$k = \left(\frac{4\pi}{h\lambda_s k_B T} \right)^{1/2} \cdot |V|^2 \cdot \sum_0^{\infty} \left[\frac{(1-\xi)^{1/2} e^{-(1/4)\gamma\xi^n |H_n(x)|^2}}{n!} \right] \cdot e^{-(\lambda_s + \Delta G^\circ + n h \nu_F)^2 / (4\lambda_s k_B T)}$$

where ξ and γ are the distortion and displacement parameters defined respectively as

$$\xi = \frac{(\nu_I - \nu_F)}{(\nu_I + \nu_F)} \quad \text{and} \quad \gamma = \sqrt{k_I k_F} \cdot \frac{(q_I - q_F)^2}{h(\nu_I + \nu_F)}$$

where k_I and k_F are the force constants on the reactant and product side of the barrier, and q_I and q_F are the respective equilibrium positions. The variable x in the Hermite polynomial H_n is defined as

$$x = \sqrt{\frac{\gamma(1-\xi)}{2\xi}}$$

All the necessary excited-state parameters (frequencies, force constants, and equilibrium geometries) can be obtained from MO calculations or, in a few cases, from excited-state Raman measurements. The above rate expression, like the standard Marcus–Jortner equation, can be readily modified to include more than one vibrational mode. The difference between the two approximations should be most pronounced when $h|\nu_I - \nu_F| > k_B T$ and $h|\nu_I - \nu_F| > \lambda_s$. The second condition is more likely to be satisfied for electronic excitation transfer than for charge transfer.

7 Charge-Transfer Excited States of Transition Metal Complexes

John F. Endicott

7.1 Definitions and General Concepts

Charge transfer (CT) excited states are generated by the absorption of energy, usually light energy, by a molecular or supramolecular system. The distribution of electron density of these species differs from that of the ground state. The change in the charge distribution can be associated with specific atoms, or groups of atoms, and this association is the basis for classification and interpretation of the spectra and for detailed mechanistic discussions. The identification of specific groups of atoms with this charge redistribution does lead to useful simplifications in the discussion of CT spectroscopy and CT excited-state properties. The discussion of observations on specific systems later in this chapter will begin with ion-pair systems in which this concept is relatively well defined and then progress to the discussion of systems in which the simplified picture is less and less appropriate. A number of general theoretical concepts need to be mentioned and terms need to be defined before the observations are dealt with.

7.1.1 Basic Concepts

Only condensed-phase systems will be considered in this chapter. General systematic approaches to the spectroscopy and properties of CT excited states were described in detail by Mulliken [1]. Approaches to the CT spectroscopy of transition metal complexes were developed by Jørgensen [2]. Lever developed these approaches further and summarized their application to a range of transition metal complexes [3]; Solomon and Hanson [4] considered their application to metalloenzymes and model systems. Endicott [5], Hovarth and Stevenson [6], and Ferraudi [7] discussed the photochemistry and photophysics of transition metal CT systems, including the applications of the various theoretical models. These works may be consulted for

more detail than is possible here and for somewhat different perspectives than those presented here.

It is useful to first consider a system $\{D^-, A\}$, composed of a well-defined electron donor, D^- , and a well-defined electron acceptor, A . This idealized system will exhibit a simple absorption band corresponding to the process described in Eq. 1:

Here, the asterisk designates an electronically and vibrationally excited system. The CT excited state so generated, the Franck–Condon (FC) excited state, will have the same nuclear coordinates as the ground state. The nuclei in the FC state will not generally be at equilibrium with the new charge distribution. Nuclear relaxation (bond length and bond angle changes, solvent reorganization, etc.) of the FC state may generate a vibrationally equilibrated excited state (VEqES). The difference in the energy of the FC and VEqES, λ_{vib} , will appear as heat deposited in a condensed phase environment. Figure 1 qualitatively illustrates these energy relationships. The rate at which vibrational energy in the electronically excited system is converted into heat in the solvent medium appears to vary with the size of the molecular vibrational quanta and with the coupling of the vibrational motion to the solvent vibrational modes. Since many of the physical and chemical processes characteristic of CT excited states occur in very short time regimes (process lifetimes of ps or shorter), the rate of vibrational cooling can be an important factor in the discrimination between potential relaxation channels.

The simplest assumption about excited-state physical and chemical behavior is that all processes are sequential: relaxation within the excited-state potential-energy (PE) manifold to the lowest energy vibrational level of the electronic excited state (the VEqES), then a reaction to form products or crossing to lower-energy potential-energy surfaces (e.g., the ground state in Figure 1). The excited states that conform to this limit can be treated as normal chemical species, species that are at equilibrium with their environment in all but the electronic coordinates. In general, one expects some relaxation of interelectronic repulsion, ΔE_{el} , to accompany the FC to VEqES relaxation process, so that Eq. 2,

$$h\nu_{\text{max}} = E^{00} + \lambda_{\text{vib}} + \Delta E_{\text{el}} \quad (2)$$

gives the energy of the absorption maximum.

7.1.2 The Idealized Limit of Weak D/A Electronic Coupling (LWEC)

While the energy and free energy must be the same for the vertical transition, $h\nu_{\text{max}}$, the subsequent vibrational relaxation of the excited state to the VEqES may result in significant changes of solvation in a $\{D^-, A\}/\{D, A^-\}$ system. This will result in differences of the energy, E^{00} , and free energy, ΔG^{00} , of the VEqES. In the limit of very little D/A coupling that is considered here, and for the free-energy interpretation of the transition energy ($h\nu_{\text{max}} = \Delta G^{00} + \chi_{\text{vib}}^{\text{op}} + \Delta G_{\text{el}}$),

Figure 1. Qualitative illustration of the energy relationships in an idealized two-state system.

$\Delta G^{00} \cong -F[E^\circ(A/A^-) - E^\circ(D/D^-)]$, and $\Delta G_{el} = \Delta E_{el} \sim 0$; F is Faraday's constant and $E^\circ(X/X^-)$ is the standard electrode potential for the X/X^- redox couple. In this limit, the vibrational-free energy difference between the nuclear coordinates of the excited-state free energy minimum and those of the ground-state free energy minimum, χ_{vib}^{op} , has the same meaning as the reorganizational energy for the thermally activated electron-transfer reaction, χ_r^{th} : $\chi_{vib}^{op} \cong \chi_r^{th}$. Values of χ_r^{th} can be obtained as the average of the reorganization energies, χ_{exch}^{th} , for the thermally activated, self-exchange electron-transfer reactions (Eq. 3) of the donor and acceptor redox couples

(M^{x+} and $\# M^{y+}$ differ only in oxidation state and, possibly, in isotopic composition). Since the electrode potentials and the thermally activated self-exchange

electron-transfer rates are, in principle, independently measurable, this limit provides a very useful point of departure for the discussion of the charge-transfer excited states of transition metal complexes.

7.2 Charge-Transfer Absorption Spectroscopy

The characteristics of the absorption of light by matter can be used to obtain a great deal of information about the structure and properties of that matter. For the molecular substrates considered here, the observable features of the absorption process and the correlated molecular properties can be summarized as follows:

- a) The energy of the absorption maximum ($h\nu_{\max}$) is correlated with the energy difference of the two electronic configurations and the differences of molecular geometry of the vibrationally equilibrated electronic excited and ground states.
- b) The oscillator strength (or integrated intensity; proportional to $\epsilon_{\max}\Delta\nu_{1/2}$) correlates with the square of the electronic matrix element (H_{ge}), or the symmetry selection rules for the absorption.
- c) The full width at half maximum ($\Delta\nu_{1/2}$) correlates with the differences in geometry of the ground and excited state.
- d) The asymmetry (or skewness) of the absorption band can be related to vibronic progressions that result from the excited-state distortion.

If there is configurational mixing between two electronic states, the ground-state (G) wave function is given to first order by Eq. 4, the excited state (E) wave function by Eq. 5.

$$\Psi_G = (\Psi_G^0 + \alpha_{GE}\Psi_E^0)/(1 + \alpha_{GE}^2)^{1/2} \quad (4)$$

$$\Psi_E = (\Psi_E^0 - \alpha_{EG}\Psi_G^0)/(1 + \alpha_{EG}^2)^{1/2} \quad (5)$$

In these equations, $\alpha_{GE} = H_{GE}/E_{GE}^0$ is the mixing coefficient and Ψ_1^0 is the initial- or diabatic-state wave function [1]. For a well-defined charge-transfer transition, α_{GE}^2 and α_{EG}^2 are both much less than one and approximately equal. In real systems, α_{IJ}^2 can span a range of values from about zero (for the LWEC in Section 7.1.2) to about one (for highly delocalized systems). To the degree that the mixing coefficients differ from zero, factors other than those discussed in Section 7.1.2 will contribute to the transition energy.

7.2.1 The Energies of Charge-Transfer Absorptions

Equations 4 and 5 provide a simple basis for defining the energy differences between two electronic states. Thus, the dominant contribution to $h\nu_{\max}$ in solution should

be the difference in the vertical ionization energies of the vibrationally equilibrated states G and E , $IE_s^v(G)$, and $IE_s^v(E)$. In addition, state E must be generated with the nuclear coordinates of the ground state, and this leads to a correction corresponding to the differences in vibrational (including solvational) energies. This is denoted by λ_{vib} in Figure 1. Finally, there will be some electronic relaxation, ΔE_{el} , associated with the changes of nuclear coordinates in the excited state. This leads to Eq. 6 [1, 8–10],

$$h\nu_{\text{max}} = IE_s^v(G) + EA_s^v(E) + \lambda_{\text{vib}} + \Delta E_{\text{el}} \quad (6)$$

where $-IE_s^v(E) = EA_s^v(E)$. Since α_{GE} is small, and since Ψ_G^2 and Ψ_E^2 are proportional to charge densities of electrons at the different atomic or molecular subunits involved in charge-transfer transitions, $IE_s^v(D)$ and $EA_s^v(A)$ are often substituted for the first two terms in Eq. 6. These quantities are well defined only in the diabatic limit ($\alpha_{GE} = 0$). When the donor and acceptor moieties can be investigated separately, as is often the case for coordination complex systems, it is then convenient to define $IE_s^v(D)$ and $EA_s^v(A)$ in terms of these moieties and to introduce an additional term, C_{DA} , into Eq. 6 to account for the alteration of their values as a result of the covalent linkage. Gorelsky et al. [10] have tabulated values of IE_s^v for a number of transition metal complexes; however, these quantities are not generally available or readily determined.

Experimental Charge-Transfer absorption-energy correlations useful for transition metal complexes

Variations on Eq. 6 substitute “optical electronegativities”, $\chi_{\text{el}}(X)$ [2, 3, 5], or solution electrode potentials [3, 10–12] for $[IE_s^v(D) - EA_s^v(A)]$. Both approaches have been used extensively. The optical electronegativity approach has considerable appeal, since it makes use of common chemical concepts. However, the correlation of $h\nu_{\text{max}}$ with $[\chi_{\text{el}}(M) - \chi_{\text{el}}(X)]$ (for a metal center M and a ligand center X) is empirical and requires a large number of correction terms in order to apply to a variety of complexes [13]. Moreover, this approach involves orbital-based parameters, and that presumes that it is possible to identify an explicit donor orbital and an explicit acceptor orbital. This is often not straightforward, as is discussed below. Nevertheless, this approach can be a useful basis for interpreting spectra and values of $\chi_{\text{el}}(M)$ and $\chi_{\text{el}}(X)$ have been published [2, 3, 5]. The use of electrode potentials as a substitute for vertical, solution ionization energies leads to straightforward empirical correlations with $h\nu_{\text{max}}$. Such correlations employ independently measured parameters and do not require the explicit identification of the donor and acceptor orbitals, but they do introduce free-energy quantities into an energy correlation. Since the optical transitions are vertical, with the change of electronic state induced without a change of nuclear coordinates, the energy changes (Section 7.1.2) are equal to the free-energy changes for this process [14]. Assume, for $\{D^-, A\} \rightarrow \{D, A^-\}$ that $h\nu = E^{00} + \lambda_{\text{vib}} + (\text{other terms})$, as in Figure 1. Then the energy of the absorption maximum of the CT transition may be represented as in Eq. 7,

$$h\nu_{\text{max}}(DA) = F[E^\circ(A/A^-) - E^\circ(D/D^-)]_{\text{LWEC}} + \frac{1}{2}(\chi_r^D + \chi_r^A) + \gamma_{DA} \quad (7)$$

where the terms on the right-hand side are all free-energy terms (defined in Section 7.1.2; see also [15–18]) and experimentally determined for the individual A/A[−] and D/D[−] couples. The reorganizational free energies for the bimolecular M/M[−] self-exchange reactions (see Eq. 3) are represented as χ_r^M in Eq. 7 for conciseness (rather than as $\chi_{\text{exch}}^{\text{th}}$ used in Section 7.1.2; also note that $\chi_r^M = 4\Delta G^\ddagger(\text{M/M})$ [19, 20]). The deviations from the limit of weak D/A electronic coupling that arise from covalently linking the donor and acceptor are represented by γ_{DA} . The contributions to γ_{DA} can arise from charge delocalization, direct D/A covalent contributions (e. g., as in metal–metal bonding), differences in the solvation energy contributions, etc. It is useful to view γ_{DA} as a measure of the differences between the diabatic (separate fragments; no interaction between D and A) and the adiabatic (allowing for interactions between D and A) contributions to these terms. In the limit that $|\Delta G^\circ| < \chi_r$ and $|H_{\text{DA}}| < (\chi_r + \Delta G^\circ)/2$ (for χ_r and ΔG° being the respective diabatic parameters) Brunschwig and Sutin [21] have evaluated γ_{DA} for a two-state model as in Eq. 8:

$$\gamma_{\text{DA}} \cong 2H_{\text{DA}}^2 \Delta G^\circ / (\chi_r + \Delta G^\circ)^2 + 2H_{\text{DA}}^4 \Delta G^\circ (3\chi_r - \Delta G^\circ) / (\chi_r + \Delta G^\circ)^5 \quad (8)$$

Of course, this corresponds to an adiabatic potential-energy surface with two potential-energy minima separated by a well-defined barrier. Note that γ_{DA} contains anharmonicities induced into χ_r^M by D/A interactions as well as energy corrections that originate from D/A coupling. To some extent (i.e., as in first-order perturbation theory or in a Taylor's series expansion around the diabatic values of χ_r^M and ΔG°), γ_{DA} may be linearized so that $\gamma_{\text{DA}} \cong \sum_M^{D,A} [(\gamma_\chi^M(\chi_r^M) + \gamma_G^M(\Delta G^\circ))]$, $\chi_\rho^M \cong (\chi_r^M + \gamma_\chi^M)$ and $E_{1/2}^a \cong [E^\circ(\text{M/M}^-) + \gamma_G^M]$. Then Eq. 9 is an experimentally useful expression, in which the potentials for the donor and acceptor centers in the actual molecule of interest have been substituted for the standard potentials of the separate, non-interacting D and A fragments:

$$h\nu_{\text{DA}} = F[E_a^\circ(\text{A/A}^-) - E_a^\circ(\text{D/D}^-)] + \frac{1}{2}(\chi_\rho^{\text{D}} + \chi_\rho^{\text{A}}) + \dots \quad (9)$$

Additional contributions to $h\nu_{\text{max}}$ can arise from configurational mixing and from the differences in the species involved in the optical and electrochemical processes. However, the mixing between the ground and CT-excited states, described in Eqs. 4 and 5, results in smaller differences between the ground-state and excited-state nuclear coordinates; this cancels (in the harmonic-oscillator limit) the effect of the increase of their energy difference in coordinates of the unmixed (or diabatic) states. These issues will be discussed further within the context of MLCT excited states. The actual values of χ_ρ^M to be used in Eq. 9 are not generally available from an independent experimental measurement. If the contributions of γ_{DA} were small, the appropriate values of χ_ρ^M will be very similar to those of χ_r^M . In a series of closely related complexes, the variations of χ_ρ^M might be based on: a) The measured values of χ_r^M , adjusted to give the best empirical fit within the series; b) An appropriate theoretical model to estimate the γ_{DA}^M correction terms; or c) The difference

between the observed absorption maxima and $F[\Delta E_a^\circ(\text{A}/\text{A}^-) - \Delta E_a^\circ(\text{D}/\text{D}^-)]$. Examples are developed in the sections below.

Orbital based energy arguments

In the simplest case, a singlet–singlet CT transition, the electronic transition energy can be related to the energy differences, $\Delta\epsilon(\psi)$, between the molecular orbitals occupied in the ground state (HOMO – n) and in the excited state (LUMO + n). When the significant contributions are only from the highest occupied ($n = 0$) and lowest unoccupied ($n = 0$) molecular orbitals, then Eq. 10 results [9],

$$\Delta E(\psi) = \epsilon_{\text{LUMO}} - \epsilon_{\text{HOMO}} - J_{\text{HL}} + 2K_{\text{HL}} \quad (10)$$

where ϵ_{LUMO} and ϵ_{HOMO} are the LUMO and HOMO orbital energies and J_{HL} is the Coulomb integral and K_{HL} is the exchange integral. All the components of Eq. 10 must be calculated from a molecular-orbital model. The close energies and number of the diabatic states, the large number of valence shell electrons, and so forth for transition metal systems makes accurate calculations difficult and time-consuming. Simple one-electron approaches to orbital energies are sometimes used, but these need to be corrected for the interactions between electrons to be useful [9].

7.2.2 Charge-Transfer Excited-State Terms and Assignments

The electronic symmetry of the excited state is determined by the symmetries of partly occupied molecular orbitals. Since configurational mixing is most important between states of the same symmetry, the state symmetries can be determined on a relatively simple basis. Thus, if one can identify the HOMOs of the D and A molecular fragments corresponding to the excited state, then the symmetry of that state will be the result of the direct product of the fragment symmetries reduced in the point group of the molecule. For example, consider the lowest-energy ligand-to-metal charge-transfer (LMCT) excited states of $\text{Co}(\text{NH}_3)_5\text{Br}^{2+}$. The electron transferred to cobalt will be in a $d\sigma$ orbital of $a_1(d_{z^2})$ or $b_1(d_{x^2-y^2})$ symmetry in the C_{4v} point group. The bromine atom has the electronic symmetry resulting from one partly occupied p orbital, a_1 or e in C_{4v} . The resulting ligand-to-metal charge-transfer excited states have A_1 , B_1 and E symmetries. The A_1 state involves only σ -type orbitals and is often classified as a σ -LMCT state, while the E state corresponds to a hole in the $p\pi$ orbitals and is often classified as a π -LMCT state. In another example, the LUMO on pyridine has b_2 symmetry while the partly occupied orbitals of $\text{Ru}(\text{NH}_3)_5^{3+}$ will have a_2 , b_1 , and b_2 symmetry in the C_{2v} point group, and the lowest-energy metal-to-ligand charge-transfer excited states will have B_1 , A_2 , and A_1 symmetry (or B and A symmetry in the actual C_2 symmetry of the molecule). The absorption bands that dominate the observed spectrum depend on a combination of selection rules and orbital overlap. These issues are discussed in the next section.

7.2.3 The Analysis of Spectroscopic Absorption Bands

For most transition metal complexes in solution, broad and intense charge-transfer absorption bands are observed. The intensity and band shape contain information about the structure of the electronic excited state.

The oscillator strength or intensity of the absorption band

The electronic-transition dipole moment for the $G \rightarrow E$ transition is defined by $\mathbf{M}_{GE} = \langle \Psi_G | \Delta\mu_{GE} | \Psi_E \rangle$ where the Ψ_i are the state wave functions and $\Delta\mu_{GE}$ is the difference in dipole moment of the ground and excited states [22]. The intensity of the transition is proportional to $|\mathbf{M}_{GE}|^2$. The broad absorption bands usually observed in transition metal systems are composed of progressions in the vibrational modes that correlate with the differences in nuclear coordinates between the vibrationally equilibrated ground and excited state. Since the energy difference between the donor and acceptor is generally solvent-dependent, the distribution of solvent environments that is characteristic of solutions may also contribute to the bandwidth (see further discussion of this point in the sections below). If the validity of the Born–Oppenheimer approximation is assumed, the intensity of each of these vibronic components is given by Eq. 11,

$$\mathbf{M}_{G0 \rightarrow En} = \langle \mathbf{M}_{GE} \rangle S_{G0, En} \quad (11)$$

where $\langle \mathbf{M}_{GE} \rangle$ is a mean value of \mathbf{M}_{GE} , assumed to be independent of the nuclear coordinates, $S_{G0, En} = \langle \phi_{G0} | \phi_{En} \rangle$ is the vibrational-overlap integral and ϕ_{Im} are the vibrational wave functions for the m th vibrational mode of the I th electronic state [22]. The oscillator strength for the $G0 \rightarrow En$ vibronic absorption is given by Eq. 12 (for $\nu_{G0 \rightarrow En}$ in cm^{-1} ; g is a multiplicity factor).

$$\begin{aligned} f_{G0 \rightarrow En} &= \frac{8\pi^2 g m_e c \nu_{G0 \rightarrow En}}{3 h e^2} |\langle \mathbf{M}_{GE} \rangle|^2 |S_{G0, En}|^2 \\ &= 4.70 \times 10^{29} \nu_{G0 \rightarrow En} |\langle \mathbf{M}_{GE} \rangle|^2 |S_{G0, En}|^2 \end{aligned} \quad (12)$$

Summation of $f_{G0 \rightarrow En}$ over all the allowed vibronic transitions, n , gives the theoretical absorption band envelope. When one is dealing with a single excited state, the electronic absorption band energy, intensity and band shape can provide much pertinent information. The substitution of molar absorptivity, $\epsilon_{v(m)}$, for oscillator strength (for light of energy $h\nu_m$) results in Eq. 13 [23, 24] (assuming that the electronic transition dipole moment, \mathbf{M}_{GE} , is the same for all vibrational states),

$$\epsilon_{v(m)} = \frac{4\pi^2 |\mathbf{M}_{GE}|^2 \nu_m N_A}{(3 \times 10^{10} \ln 10) n h c} \sum_j \frac{\Gamma \langle \phi_E | \phi_j \rangle^2}{4\pi^2 (\nu_m - \nu_0 - \nu_j)^2 + \Gamma^2} \quad (13)$$

where n is the index of refraction, c is the speed of light, N_A is Avagadro's number,

ϕ_j are excited-state vibrational wave functions, ϕ_G is the ground-state vibrational wave function, $\langle \phi_j | \phi_G \rangle$ is a vibrational-overlap integral, $h\nu_0 = \Delta E_{GE}^{00}$, $h\nu_j$ is the correlated excited-state vibrational quantum, and Γ is the lifetime limited line width. The summation of Eq. 13 over all the allowed vibronic transitions, j , gives the theoretical band envelope. The results of such summations are usually expressed in terms of $(H_{GE}\Delta\mu_{GE})^2$. Then the intensity becomes inversely proportional to $\nu_{G0 \rightarrow Ej}$ (see definitions above, Eqs. 4 and 5 and Ref. [25]). Then the molar absorptivity at the frequency ν_m is given by equations of the form of Eq. 14 [24–27],

$$\varepsilon_{\nu_m} = \frac{8N\pi^3}{3000h^2c\nu_m \ln 10} n^3 H_{GE}^2 (\Delta\mu_{GE})^2 (FC) \quad (14)$$

in which n is the index of refraction and (FC) is a Franck–Condon factor. In the simpler models, the Franck–Condon factor is assumed to be a function of excitation of a single, quantized, high-frequency vibration (or of a single nuclear coordinate), $h\nu_h \geq 4k_B T$, and of classical low-frequency modes, $h\nu_s \leq 4k_B T$. In such a case (FC) can be represented as in Eq. 15 [24, 25].

$$(FC) = \sum_j F_j \{ \exp[-(\Delta G_{GE}^0 - h\nu_m + jh\nu_h + \lambda_s)^2 / 4\lambda_s k_B T] \} / (4\pi\lambda_s k_B T)^{1/2} \quad (15)$$

$$F_j = S^j [\exp(-S)] / j!; \quad S = \lambda_h / h\nu_h$$

For an absorption band with a Gaussian band shape and involving single configurational contributions, Eq. 16 may be used to obtain values H_{GE} [1, 19, 20]

$$H_{GE} \cong (0.0205) [\varepsilon_{\max} \Delta\nu_{1/2} h\nu_{\max}]^{1/2} / r_{GE} \quad (16)$$

In this equation, the energies are expressed in cm^{-1} , and r_{GE} , the distance between centers of charge in the ground and excited state, is expressed in Å. The value of r_{GE} is not generally available from ordinary optical or molecular structural measurements [28–35].

The absorption bandwidth

The absorption bandwidth is usually formulated as a function of the reorganizational energies that also contribute to Eq. 15. For a band with a Gaussian shape (i.e., for the reduced spectrum, $\nu_m \varepsilon(\nu_m)$ vs. ν_m), the full width at half the absorbance maximum is given by Eq. 17a [8].

$$\Delta\nu_{1/2} = 2[2(2k_B T \lambda_s + w) \ln 2]^{1/2} \quad (17a)$$

When there are coupled vibrations for which $h\nu_h > k_B T$, but with $\lambda_h < \lambda_s$, then these may contribute to the bandwidth and $w = h\nu_h \lambda_h$ [8]. When ΔG_{GE} is dependent on the solvent environment, this (in addition to λ_s) can also contribute to the bandwidth. Where δ is the standard deviation for the variation of $(|\Delta G_{GE}| + \lambda_s)$ with the distribution of solvates, and when $(|\Delta G_{GE}| + \lambda_s) > 0$ in a specific solvent,

the band width is approximately given by Eq. 17b:

$$\Delta\nu_{1/2} \cong 2\delta + 2[2(2k_B T\lambda_s + w) \ln 2]^{1/2} \quad (17b)$$

The skewness of the absorption band

As written, Eqs. 14 and 15 imply that the overall absorption band will only be Gaussian (in the limit of a system in which only two electronic states need to be considered) if $\lambda_h = 0$. As they are written, these equations are actually only correct for an idealized transition between states that each correspond to a single electronic configuration and for which the excited state will distort along a nuclear coordinate corresponding to a single high frequency vibrational mode, ν_h . Several factors, such as the superposition of the transitions to several states with different electronic configurations, the thermal population of ground state vibrational levels, the superposition of vibronic progressions in several vibrational modes, and so forth can result in near-Gaussian band shapes of the ambient reduced absorption spectrum. The “single configuration approximation” is nearly always better for low-temperature emission spectra than for ambient solution absorption spectra. More generally, Eq. 15 should be summed over the contributions of different high-frequency vibrational modes. Thermal population of vibrational excited states always contributes to the ambient absorption spectra of transition metal complexes since the metal–ligand vibrational frequencies are typically in the range of 600–100 cm^{-1} (high for stretches, low for bends) and $k_B T \approx 200 \text{ cm}^{-1}$. Thus, at 300 K one expects an approximately 5 % population of an M–L stretch with $h\nu \approx 600 \text{ cm}^{-1}$.

Despite the anticipated complications, Eq. 15 does define a useful limit, and it can be used as a basis for interpreting the non-Gaussian shapes of absorption bands. Of course, the interpretation is greatly facilitated by any resolution of the vibronic components implicit in Eq. 15. The contributing vibrational modes and their re-organizational energies can sometimes be determined from resonance Raman spectra [4, 23, 24, 26, 36], even when the absorption bands have no resolved structure. When resolution of the contributing vibrational modes is possible and λ_r values can be estimated, it is then possible to infer the molecular structure of the excited state.

7.3 Charge-Transfer Emission Spectroscopy

The interpretations of CT absorption and emission spectroscopy differ more in detail than in principle. The major distinction for transition metal systems is that while the absorption process usually occurs without a change of spin multiplicity, the emission almost always does involve a change of electronic spin multiplicity. This is the case because upper excited-state relaxation processes, including those that are nominally spin forbidden, tend to be very rapid (10^{11} s^{-1} or faster), and the only electronic excited states with lifetimes long enough to produce a significant, readily detectable emission are those that differ in spin multiplicity from the ground state. Exceptions might in principle arise for systems in which there is little or no

excited-state distortion ($\lambda_r \approx 0$), but such a situation is very unlikely for a charge-transfer process. The spin-orbit coupling is large enough for the heavier metals so that spin multiplicity distinctions cannot be made.

7.3.1 The Interpretation of Charge-Transfer Emission Spectra

The energies of charge-transfer emission bands can be treated very similarly to the absorptions, as described in Eqs. 6–8; this is done by merely replacing the reorganizational terms by their negatives: $h\nu_{\max}^{\text{em}} = E_{\text{EG}}^{00} - \lambda_{\text{vib}}'$. However, the substitution of electrode potentials for E_{EG}^{00} will also require a $T\Delta S$ correction if there is a change of spin multiplicity (ca. 230 cm^{-1} for a triplet-singlet transition at 300 K).

The intensity and shape of the emission band are treated in a closely related way. For an emission, the intensity function in the single high-frequency vibrational-mode limit is given by Eqs. 18 and 19 [24–26, 37–39].

$$I(\nu_{\text{m}}) = \frac{64\pi^4}{3h^3c^3 \ln 10} \nu_{\text{m}} n^3 H_{\text{GE}}^2 (\Delta\mu_{\text{GE}})^2 (\text{FC}) \quad (18)$$

$$(\text{FC}) = \sum_j F_j \{ \exp[-(\Delta G_{\text{GE}}^0 + h\nu_{\text{m}} + jh\nu_{\text{h}} + \lambda_{\text{s}})^2 / 4\lambda_{\text{s}}k_{\text{B}}T] \} / (4\pi\lambda_{\text{s}}k_{\text{B}}T)^{1/2} \quad (19)$$

$$F_j = S^j [\exp(-S)] / j!; \quad S = \lambda_{\text{h}} / h\nu_{\text{h}}$$

7.4 The Classification of Charge-Transfer Absorption Bands

Charge-transfer absorption bands are generally put into categories based on the general nature of the donor and of the acceptor. Within molecules, these categories are named according to the following pattern: donor-to-acceptor-charge-transfer (DACT). The most common of such intramolecular charge-transfer categories are: metal-to-ligand (MLCT), ligand-to-metal (LMCT), metal-to-metal (MMCT or MM'CT); ligand-to-ligand (LLCT or LL'CT). The common usage is a little different for charge-transfer transitions between different molecules: charge-transfer-to-solvent (CTTS), or, for charge transfer within ion pairs, ion-pair-charge-transfer (IPCT) or outer-sphere-charge-transfer (OSCT; this nomenclature could also be used for CTTS).

7.5 The Electronic States Generated by Charge-Transfer Absorptions

Excited states are, by definition, always transient. Their lifetimes vary from a few femtoseconds to more than a day, depending on the system and the conditions. The

shortest-lived excited “states” are very difficult to characterize. Two classes of electronic excited states can be reasonably well characterized and are important in discussions of excited-state chemistry or physics: a) The initial excited “state” generated by light absorption, the Franck–Condon (FC) excited state; b) Excited states that are in thermal equilibrium with their environment only in the sense that they have relaxed from the nuclear coordinates of the ground state to the nuclear coordinates characteristic of the potential-energy minimum of an excited-state electronic surface, the vibrationally equilibrated excited states (VEqES). These two states are illustrated in Figure 1 for the simplest two-state limit.

7.5.1 The Franck–Condon State in Transition Metal Complexes

Transition metal complexes typically have several electronic configurations, which differ relatively little in energy. These configurations will generally mix and give rise to several electronic excited states. These are properties that give transition metal complexes their remarkable structural and catalytic properties. However, these same properties generally make Eq. 1 and Figure 1 only useful in the definition of an idealized limit for the interpretation of the properties of actual transition metal systems. This issue is especially a problem for the interpretation of Franck–Condon-state properties. In general, the Franck–Condon excited states of transition metal complexes should be regarded as mixtures of a number of different electronic configurations. The description of Franck–Condon states is a matter of continuing investigation and some controversy. This is an issue of some importance in understanding these systems since the electronic configuration of the Franck–Condon state is likely to be an important factor in determining its relaxation pathway. Upper excited state and “prompt” chemical and physical processes are not uncommon in such systems.

7.5.2 The Vibrationally Equilibrated Excited States (VEqES)

To a significant extent, the vibrationally equilibrated excited states (VEqES) can be treated as a well-defined thermodynamic system. The molecular geometry, the solvation environment, and so forth can, in principle, be inferred from the emission band shape (e. g., as in Eqs. 17 and 18) or they can be probed by the use of resonance Raman and time-resolved Raman and infrared techniques. Typically, the VEqES is a better oxidant and reductant than the ground state, and this is a very important aspect of the chemistry of charge-transfer excited states.

7.6 Excited-State Relaxation Processes

Excited-state lifetimes constitute an important constraint on the properties and potential uses of charge-transfer excited states. The lifetime behavior of the VEqES

can be addressed in a reasonably systematic manner. The factors controlling the lifetimes of the Franck–Condon and intermediate excited states of transition metal complexes are not at all well understood.

7.6.1 Vibrationally Equilibrated Excited States Relaxation Processes

Any excited-state relaxation process necessarily involves the dissipation of energy from the electronically excited molecular system to the environment. This energy may appear as light, in emission as discussed above, as heat, as electrical energy (in some heterogeneous systems) and/or in some chemical form. The emphasis in this chapter is on the physical processes.

The heat-generating physical relaxation processes are generally referred to as “nonradiative relaxation” processes. These processes are, in principle, closely related to chemical reaction processes. The rates of the nonradiative relaxation of an excited state depend on several factors. Among these are the difference in energy between the VEqES and the ground state (the “energy gap” ΔE_{EG} , or the driving force), the density of acceptor states, the coupling to the solvent environment, and the coupling of acceptor (or product vibrational) states to the VEqES (usually expressed in terms of $S = \lambda_a/h\nu_a$ for the acceptor vibrational mode a , and for λ_a , the contribution of $h\nu_a$ to the reorganizational energy). Two limiting regimes should be considered: 1) The “high-temperature” limit, in which $h\nu_h > 4k_{\text{B}}T > h\nu_s$; 2) The “low-temperature” limit in which $4k_{\text{B}}T \ll h\nu_s < h\nu_h$. (The “classical” limit corresponds to $4k_{\text{B}}T \gg h\nu_h > h\nu_s$; this limit does not correspond well to observed excited-state relaxation processes).

In the high-temperature limit, and for a single high-frequency acceptor mode, the relaxation rate can be represented as in Eq. 20 [22, 25, 37, 38, 40–43].

$$\begin{aligned}
 k_{\text{nr}} &= \frac{4\pi^2}{h} H_{\text{GE}}^2 (\text{FC}) \\
 (\text{FC}) &= \sum_h \sum_j F_j \{ \exp[-(\Delta G_{\text{EG}}^0 + jh\nu_h + \lambda_s)^2 / 4\lambda_s k_{\text{B}}T] \} / (4\pi\lambda_s k_{\text{B}}T)^{1/2} \\
 F_j &= S^j [\exp(-S)] / j!; \quad S = \lambda_h / h\nu_h
 \end{aligned} \tag{20}$$

In effect, Eq. 20 describes a thermally activated crossing from the VEqES to the j th high-frequency (acceptor) vibrational level, for which the activation barrier is $\Delta G^\ddagger(j) = (\Delta G_{\text{EG}}^0 + jh\nu_h + \lambda_s)^2 / 4\lambda_s k_{\text{B}}T$. This limit weights the contributions of different high-frequency vibrations in proportion (through S) to their contributions to the total reorganizational energy. The same weighting is characteristic of absorption and emission. This has the effect of making the same high-frequency modes equally important in the radiative and nonradiative processes. In this limit, emission band-shape analysis can provide information about the molecular geometry of the VEqES and it can provide parameters required for the calculation of k_{nr} .

In the low temperature limit, $k_B T \ll h\nu_s < h\nu_h$. For this condition, the non-radiative relaxation rate constant is approximately temperature-independent and is given in the single-mode limit by Eq. 21 [40, 41],

$$k_{nr}^o = H_{GE}^2 [8\pi^3 / (h^3 \nu_M \Delta E_{GE}^{00})]^{1/2} \exp(-\gamma \Delta E_{GE}^{00} / h\nu_M) \quad (21)$$

$$\gamma = \ln[\Delta E_{GE}^{00} / \lambda_M] - 1$$

where $h\nu_M$ is the maximum-frequency vibrational mode that is coupled to the relaxation coordinate; $h\nu_M$ contributes λ_M to the total reorganizational energy λ_{vib} . The highest-frequency vibrational modes are strongly favored in this limit, since they provide the best vibrational overlap [40–42, 44]. In this limit, the weighted vibrational frequencies, those that make the dominant contributions to k_{nr}^o , are different for emission spectra (e. g., as in Eqs. 17 and 18) and for nonradiative relaxation [40]. The assumption that the vibrational modes that dominate the emission band shape are also the modes that dominate k_{nr}^o in the low-temperature limit can result in an error in k_{nr}^o of several orders of magnitude [40]. In this limit, isotopic substitution (for nuclei contributing to ν_M) should result in large changes of k_{nr}^o [41]. The lowest-energy, triplet MLCT excited state of the $\text{Ru}(\text{bpy})_3^{2+}$ complex is an example of a photosystem with a bound, well-characterized VEqES [7, 45]. This metal-to-ligand charge-transfer (MLCT) state has nominal triplet spin multiplicity, although spin–orbit coupling results in the splitting of this state into components [45–47], and the spin-forbidden relaxation to the singlet ground state is relatively slow (ca. 600 ns in water under ambient conditions) [7, 11]. Excitation into the $^1\text{MLCT}$ excited state has been found to produce a Franck–Condon excited state which relaxes to the vibrationally excited $^3\text{MLCT}$ state with $k_{nr} \approx 10^{13} \text{ s}^{-1}$ [48, 49]. Vibrational relaxation of the $^1\text{MLCT}$ excited states seems to be significantly slower than intersystem crossing for the $\text{Ru}(\text{bpy})_3^{2+}$ complex [48, 49].

7.6.2 Upper-Excited-State Electronic-State Relaxation

One expects events to occur so rapidly following Franck–Condon-state generation that the rates of at least some relaxation processes may be faster than the rate at which heat flows away from the relaxing molecule. This will make it difficult to apply normal kinetic models to these relaxation processes. The probability of surface crossing will depend on vibrational overlap, possibly in a manner related to that in Eqs. 20 or 21. The use of Eqs. 20 or 21 does presume some form of the simple limiting model, illustrated in Figure 1, in which vibrational relaxation is assumed to be rapid compared to the crossing between states with different electronic configurations. This presumes that the coupling matrix element is sufficiently small, so that the potential-energy surfaces of the electronic states involved in the crossing can be meaningfully distinguished. When H_{ij} is very large and/or the states are close in energy, this approach is not likely to be useful. In such instances, it may be more useful to consider the crossing to be from a vibronic state, with a wave function of the form given by Eq. 22 [48–53],

$$\Psi_{ij} \cong \psi_{ab}^{\text{el}}(\phi_{a,i} + \alpha_{ab}\phi_{b,j}) \quad (22)$$

where ψ_{ab}^{el} is an adiabatic electronic wave function, ϕ_{kl} are vibrational wave functions and α_{ab} is a mixing coefficient. This leads to a model for upper-state relaxation that is essentially a cascade through a series of vibrational states of mixed electronic parentage. In this limit, the electronic configurations are mixed and relaxation depends largely on the rate of energy flow from the molecular vibrational states to the solvent. If the molecular vibrational quanta are large, this can be a relatively slow (ca. ps) process. Very few systematic studies are available. It does seem that upper-state crossings between electronic configurations are very rapid in transition metal complexes, often with subpicosecond lifetimes [48, 50–53].

7.7 Observations on the Weak Electronic Coupling Limit: Ion-Pair Charge-Transfer Absorption Bands

One would expect the weak electronic coupling limit approach, that is, for $\gamma_{\text{DA}} \approx 0$ in Eq. 7, to apply best to systems in which the donor and acceptor are not covalently linked. Ion pairs form one class of such systems. Although D/A coupling is necessarily weak in ion pairs of transition metal complexes, it is often strong enough to give rise to an observable optical response, and systematic studies are possible. These studies amount to an experimental definition of the optical behavior of charge-transfer systems in the weak-coupling limit. Cannon [15] and Endicott and coworkers [16, 17] have reported free-energy analyses of spectra similar to those employed here. Lever and coworkers [10] have used a closely related energy analysis (to obtain vertical, solution ionization energies).

7.7.1 The Correlation of Observed Ion-Pair Charge-Transfer Energies with Experimental Electron-Transfer Parameters

If we assume that the reorganizational free-energy contributions to Eq. 7 are a linear combination of those of the constituent couples, $\chi_r^{\text{DA}} = (\chi_r^{\text{D}} + \chi_r^{\text{A}})/2$, then $h\nu_{\text{max}}$ can be factored into contributions of the donor and the acceptor. Since the electrode potentials are determined for the separated donor and acceptor species, the actual free-energy change associated with the ion pairs contains a correction for the ground state (K_0) and excited state (K_0') association (a “work term” that is written in terms of formation constants), Eq. 23.

$$\Delta G_e - \Delta G_g = FE_a^\circ(\text{D}/\text{D}^-) - FE_a^\circ(\text{A}/\text{A}^-) + RT \ln(K_0'/K_0) \quad (23)$$

The work term correction, $RT \ln(K_0'/K_0)$, is ignored in the discussion below. There have been several general treatments and discussions of ion-pair charge-transfer (IPCT) spectra [10, 15, 54–56]. In the context of Eq. 7 as a systematic basis for

interpreting charge-transfer spectra, ion-pair spectra are a plausible model for the limit of $\gamma_{\text{DA}} \cong 0$. A representative sample of IPCT spectra has been assembled in Table 1 [10, 18, 55–72]. Electrode potentials [58, 73–78] and electron-transfer reorganizational energies [58, 74, 76, 77, 79–82] for the constituent couples of these ion pairs are presented in Table 2. The reorganizational energies in Table 2 are obtained from the reported rate constants for self-exchange reactions (Eq. 3), except for the halides and NCS^- for which best-fit (to the IPCT data for Ru^{III} ion pairs) values have been used. The observed IPCT energies for Ru^{III} , Co^{III} and $\text{Fe}(\text{CN})_6^{3-}$ acceptors are reasonably predicted by the sum of the difference in electrode potentials and the average of the free energies of activation of the self-exchange reactions of the constituent couples, Figure 2. Excluding the halides, the overall correlation based on Eq. 7 has a slope of 0.87 ± 0.06 , an intercept of $(2.0 \pm 1.2) \times 10^3 \text{ cm}^{-1}$ with $r^2 = 0.91$ (including halides for all but the reference systems results in a slope of 0.95 ± 0.04 , an intercept of $(1.2 \pm 1.2) \times 10^3 \text{ cm}^{-1}$, $r^2 = 0.94$). This can be considered to be a good confirmation of this approach since the experimental parameters used in the correlation were based on measurements of three very different quantities, and the measurements were performed in about 30 different laboratories. There do seem to be some detailed deviations from the general correlation: a) The $\text{Os}(\text{CN})_6^{4-}$ donors consistently show the largest positive differences ($\Delta h\nu_{\text{max}}$) between $h\nu_{\text{max}}(\text{obsd})$ and $h\nu_{\text{max}}(\text{calcd})$; this suggests an error (of about $3 \times 10^3 \text{ cm}^{-1}$) in one or more of the parameters listed in Table 2 for this complex; b) The values of $\Delta h\nu_{\text{max}}$ are more consistently positive for $\text{Fe}(\text{CN})_6^{4-}$ and for $\text{Co}(\text{sep})^{3+}$ than for the other acceptors; c) In general, the values of $\Delta h\nu_{\text{max}}$ are more negative for Co^{III} acceptors than for $d\pi$ acceptors (by about $1 \times 10^3 \text{ cm}^{-1}$; the correlation line for all but $\text{Co}(\text{sep})^{3+}$ has a slope of 1.3 ± 0.3 and an intercept of $-10 \pm 5 \times 10^3 \text{ cm}^{-1}$). Some of these systematic deviations reflect inconsistencies and uncertainties in the parameters used (these were often obtained under different medium conditions, and some involve spectral deconvolutions of broad, weak absorption bands). The Co^{III} acceptors are particularly interesting, since the basis for their consistency with the overall correlation is not clear. The spin-allowed electronic IPCT transition will generate a low-spin (2E_g in O_h symmetry) Co^{II} complex in each case. However, the Co^{II} species involved in the electrochemical and self-exchange kinetic measurements is in each case a high-spin complex ($^4T_{1g}$ in O_h symmetry). That these systems correlate reasonably well with those of the other acceptors suggests that the half-wave potentials are more negative and the self-exchange rate constants are larger (i. e., the reorganizational energies are smaller) for the excited-state couples involving low-spin Co^{II} than for their high-spin ground states, and that these differences very nearly cancel in the correlation in Figure 2. Overall, the observations summarized here indicate that Eq. 7 is a good basis for predicting charge-transfer energies in weakly coupled systems.

7.7.2 Electronic Coupling in Ion-Pair Charge-Transfer Systems

Equation 16 in combination with data from Table 1 implies that there is a substantial difference in the electronic coupling matrix element for the Ru^{III} and Co^{III}

Table 1. Ion-pair charge-transfer spectra: $\{M^{III}L_6^{m+}, X^{n-}\} + h\nu \rightarrow * \{M^{II}L_6, X^{(n-1)-}\}$.

acceptors, and for the halide ($H_{\text{DA}} = 760 \pm 15$ and $2460 \pm 370 \text{ cm}^{-1}$, respectively) and $\text{M}(\text{CN})_6^{4-}$ (143 ± 45 and $590 \pm 60 \text{ cm}^{-1}$, respectively) donors. This indicates that the Co^{III} /halide systems are not really weakly coupled. However, the configurational mixing energies, ϵ_{IJ} , are only about 150 cm^{-1} and this is smaller than the uncertainties noted above. The other systems are certainly reasonable models for the weakly coupled limit. That the H_{DA} values for Co^{III} acceptors are three to four times larger than for Ru^{III} acceptors is interesting. The origin of the effect is not entirely clear. It has been suggested that the $\text{M}(\text{CN})_6^{4-}$ donors form hydrogen bonds to the amines of $\text{Ru}(\text{NH}_3)_6^{3+}$ [59, 83] and this may result in better $d\pi/d\sigma$ than $d\pi/d\pi$ overlap. Also, larger values of H_{DA} have been predicted for $\text{Co}^{\text{III}}/\text{Co}^{\text{II}}$ than for $\text{Ru}^{\text{III}}/\text{Ru}^{\text{II}}$ self-exchange reactions [84]. Whatever its origin, this ordering of H_{DA} is not often characteristic of covalently linked LMCT systems.

7.7.3 Ion-Pair Charge-Transfer Absorption Band Widths

The average of the IPCT bandwidths is slightly larger than expected based only on the $k_B T$ contributions to Eq. 17a. Experimental factors may enter into this to a significant degree, owing to the contributions of higher-order aggregates [83], the very limited solubilities of some of the ion pairs, and the deconvolution problems mentioned previously. If the deviations are significant, then the contributions of δ , Eq. 17b, would be ca. $(1.5 \pm 1) \times 10^3 \text{ cm}^{-1}$.

A different issue concerns Lever's reorganizational energies (λ_r^{op} in Table 2) for the vertical ionization processes [10]. These are best-fit energy values for the individual donors and acceptors, and they are, in principle, different from the self-exchange reorganizational free energies (χ_r^{th} in Table 2). The values of λ_r^{op} are systematically larger $[(+2.4 \pm 2.6) \times 10^3 \text{ cm}^{-1}]$ than the values of χ_r^{th} for the anionic donors, but systematically smaller $[(-5.4 \pm 3.0) \times 10^3 \text{ cm}^{-1}]$ for the cationic

onic acceptors. The values of χ_r^{th} very likely contain an entropy ($T\Delta S$) contribution, and they correspond to the average of the sum of the χ_r^{th} contributions from the donor and the acceptor. The major contributions to ΔS probably arise from solvational effects. The solvation entropy of a cation is a function of its charge and size [85], as in Eq. 24:

$$\Delta S_{\text{solv}} \cong -3.3 (Z^2/r) \text{ cm}^{-1} \text{ mol}^{-1} \text{ T}^{-1} \quad (24)$$

where Z is the ionic charge, r is the effective ionic radius in Å and the parameters are evaluated in water at 25 °C. For a one electron process the entropy change associated with an acceptor or a donor is $\Delta(\Delta S) = (3.3 \times 10^3)(2Z - 1)/r \text{ cm}^{-1} \text{ M}^{-1} \text{ T}^{-1}$, so the contributions have different signs for cations and anions. For $\text{M}(\text{CN})_6^{4-}$, Eq. 24 implies $T\Delta S = -2.0 \times 10^3 \text{ cm}^{-1}$. This is similar in magnitude to the observed differences and consistent with $\chi_r^{\text{th}} = \lambda_r^{\text{op}} - \Gamma\Delta S$. That the signs of $(\chi_r^{\text{th}} - \lambda_r^{\text{op}})$ are different for donors than for acceptors may originate from some other factor, possibly a systematic error of $(2-5) \times 10^3 \text{ cm}^{-1}$ in the reference threshold ionization energy [86]. In any event, the uncertainties in the various parameters make it difficult to evaluate these differences. Overall, the values of χ_r^{th} and λ_r^{op} do vary in similar ways, as expected.

7.8 Ligand-to-Metal Charge-Transfer (LMCT) Absorption Bands

7.8.1 Energy Correlations for Simple Systems: $\text{M}^{\text{III}}(\text{NH}_3)_5(\text{X}^-)$ Complexes

When the donor is covalently linked to the acceptor one might expect Eq. 9 to fail owing to the cross terms introduced by the covalent bonding. In addition, the covalent M–X bond can give rise to four qualitatively different configurational descriptions of charge-transfer transitions in complexes with partly filled d orbitals (for ligand p, metal d orbitals): 1) $p\sigma$ -bonding to $d\sigma^*$ -antibonding; 2) ligand $p\pi$ -nonbonding to $d\sigma^*$ -antibonding; 3) $p\sigma$ -bonding to $d\pi$ -nonbonding; and 4) $p\pi$ -nonbonding to $d\pi$ -nonbonding. The transitions observed are most often assigned as in *a* and *b* in d^6 low-spin transition metal complexes, and as in *d* in low-spin d^5 complexes. Assignments are more complicated with other metal d-orbital configurations and/or in complexes with more than one donor ligand (or acceptor metal). All else being equal, transitions of types *a* and *b* tend to be higher in energy (by ca. 10 Dq) than transitions of type *d*. The effects of covalent interactions are expected to be much larger in $p\sigma/d\sigma^*$ (*a*) than in the other types of LMCT transitions. In the limit that the M–X bond is more covalent than ionic, the corresponding $p\sigma/d\sigma^*$ transition should not exhibit the properties discussed above for IPCT absorption bands and the transition should not be classified as a charge-transfer transition.

The use of electrochemical data for the actual molecule can accommodate some of the effects of covalency. In general, the observations on LMCT absorptions in the ammine complexes suggest that nonlinear, or cross-term effects make only small contributions to the transition energies. Thus, the absorption maxima of the

^a Units of $\text{cm}^{-1} \cdot 10^{-3}$ ^b ($\text{cm}^{-1} \text{ M}^{-1}$)/ 10^3

$\text{X}^- \rightarrow \text{M}^{\text{III}}$ LMCT (ligand π orbital to metal $d\pi$ or $d\sigma$ acceptor orbital) transitions in $\text{M}(\text{NH}_3)_5\text{X}^{2+}$ complexes [3, 56, 83, 87–93] very strongly correlate with $h\nu_{\max}$ of the $\{\text{M}(\text{NH}_3)_6^{3+}, \text{X}^-\}$ IPCT absorptions discussed above, Table 3 and Figure 3. The deviations are systematic: the slope of the least-squares correlation line for the data in Figure 3 is 0.84 ± 0.06 and the intercept is $-1.4 \pm 1.9 \times 10^3 \text{ cm}^{-1}$. The deviations from a 1:1 correspondence are much larger when X is a halide [3, 87, 88, 92] than when X is $\text{M}(\text{CN})_6^{4-}$ [56, 83, 90, 91, 93] (6–8 compared to $3.5 \times 10^3 \text{ cm}^{-1}$, respectively). Some of the deviations arise from differences in the $\text{M}^{\text{III}}/\text{M}^{\text{II}}$ and $\text{X}^{\cdot}/\text{X}^-$ reduction potentials in the bound and ion-pair systems. The actual reduction potentials have been measured for some of the $(\text{NH}_3)_5\text{Ru}^{\text{III}}[\text{NCM}^{\text{II}}(\text{CN})_5]^-$ complexes [83] and estimated for some of the $\text{Ru}^{\text{III}}(\text{NH}_3)_5(\text{X}^-)^{2+}$ complexes. For these complexes, the effective reorganizational free energies are $\chi_p = (5.0 \pm 1.4) \times 10^3 \text{ cm}^{-1}$, independent of whether X^- is a halide or a hexacyano complex. Similarly, a plausible correlation line can be drawn through the data in Figure 3 with a slope of one and an intercept of $-5 \times 10^3 \text{ cm}^{-1}$. In the Co^{III} complexes, the coordinated halide is probably more difficult to oxidize, while the metal is easier to reduce [73, 94] than in the corresponding ion pair, and the effect of the reduction potentials may not be particularly important. A very rough estimate suggests that χ_r/χ_p may

Figure 3. Correlation of charge-transfer absorption maxima for $M^{III}(L)_5X^{2+}$ complexes and $\{M^{III}(L)_6^{3+}, X^-\}$ ion pairs; closed circles for $M = Co$, closed squares for $M = Ru$. Data from Tables 1 and 3. The points correspond to compounds and ion pairs with the same M^{III} and X^- .

be about twice as large for the LMCT bands of the $Co(NH_3)_5X^{2+}$ complexes as for those of the $Ru(NH_3)_5X^{2+}$ complexes. The optical transition dipole lengths must be significantly smaller for the LMCT transitions of $M^{III}(L)_5(X^-)$ complexes than for the IPCT transitions of the related $\{M^{III}(L)_6, X^-\}$ ion pairs. A smaller solvent re-organizational energy is expected for the systems with the smaller dipole lengths, and this probably accounts for many of the observations noted.

Overall, the LMCT absorptions conform to expectation based on Eq. 9, but the effective values of χ_p are smaller than those for IPCT absorptions. Nonlinear covalent effects in γ_{DA} appear to be relatively small.

7.8.2 More Complex Ligand-to-Metal Charge-Transfer (LMCT) Systems

Thiaether complexes

A large number of complexes have been prepared with thiaether ligands [34, 77, 95–97]. These complexes typically contain several sulfur donor atoms. For example, several complexes of Cu^{II} with tetrathia macrocyclic ligands are listed in Table 4. These complexes typically exhibit two broad charge-transfer bands in the visible region of the spectrum. The energy differences of these bands average about the same as the energy differences of the σ -LMCT and π -LMCT bands of the $Co(NH_3)_5X^{2+}$ complexes in Table 3 ($7.7 \times 10^3 \text{ cm}^{-1}$). A similar assignment of these absorptions, $p\sigma \rightarrow d\sigma$ and $p\pi \rightarrow d\pi$ seems likely. However, the multiple donors of these relatively low-symmetry complexes (C_{2h} typical symmetry) should lead to several components of each of the bands ($A_g \rightarrow B_u$ and $A_g \rightarrow A_u$ components for each, in the simplest analysis of C_{2h} symmetry). Apparently these components are not resolved in ambient solutions. The copper(II) complexes differ from the ruthenium ammine

complexes discussed above in that the $F\Delta E_a^\circ$ and χ_ρ contributions to $h\nu_{\max}$ relate to a metastable geometry of the copper(I)/(RS⁺) species rather than to the equilibrated species. This is a result of the different ligand conformations required for the Cu^{II} and Cu^I complexes and the slow rates of conformational isomerization [97, 98]. One expects that this would lead to larger values of $F\Delta E_a^\circ$ and smaller values of χ_ρ^{Cu} than for the Ru^{III} and Co^{III} ammine complexes. This point is difficult to evaluate quantitatively, since the measured values of Cu^{II}/Cu^I potentials are for the equilibrium geometries of the complexes [98]. However it can be illustrated for the [9]aneS₃ complexes.

The Co([9]aneS₃)₂^{3+/2+}, Cu([9]aneS₃)₂^{2+/+} and Cu([9]aneS₃)(aq)^{2+/+} complexes exhibit a single relatively intense RR'S/Cu^{II} LMCT absorption band [77, 97, 99]. This is most likely a $p\sigma \rightarrow d\sigma^*$ transition. The Co([9]aneS₃)₂^{3+/2+} couple has values of $E_{1/2} = 0.42$ V, $\chi_r^{\text{Co}} = 14 \times 10^3$ cm⁻¹, and $h\nu_{\max}$ (LMCT) = 30.3×10^3 cm⁻¹ [77].

These observations, the assumption that $(\chi_r^{\text{Co}} - \chi_p^{\text{Co}}) \approx 5 \times 10^3 \text{ cm}^{-1}$ (based on the comparisons in the preceding section) and Eq. 9 imply that $(FE_a^0 + \chi_p^S/2) \approx 26.7 \times 10^3 \text{ cm}^{-1}$. This, data from Table 4, values of $E_{1/2} = 0.70$ and 0.33 V [99], respectively for the $\text{Cu}([\text{9}] \text{aneS}_3)_2^{2+,+}$ and $\text{Cu}([\text{9}] \text{aneS}_3)(\text{H}_2\text{O})_n^{2+,+}$ couples, and Eq. 9 suggest values of $\chi_p^{\text{Cu}} \approx 3 \times 10^3$ and $6 \times 10^3 \text{ cm}^{-1}$, respectively, for these complexes (in the Cu^{II} conformational geometry). Extended to the macrocyclic thiaether complexes in Table 4, this argument suggests values of $E_{1/2}(\text{Cu}^{\text{II}}/\text{Cu}^{\text{I}})$ of about $0.2\text{--}0.6 \text{ V}$ for these complexes with the Cu^{II} ligand conformation. This is reasonably consistent with experimental estimates [98].

Ligand-to-Metal Charge-Transfer (LMCT) Excited States in MX_n Complexes

There have been many spectroscopic studies of high-symmetry MX_n ($n = 4, 6$ and 8) complexes [2, 3]. When the ground state has a partly filled d-orbital sub-shell, such complexes will have a very large number of LMCT excited states [3]. For example, the “ $p\pi \rightarrow d(t_2)$ ” excited-state configurations of $\text{Fe}(\text{Cl})_4^-$ give rise to $(A_1 + A_2 + 2E + 3T_1 + 3T_2)$ LMCT excited states [from the product of the $\text{Fe}^{\text{II}}(T_2)$ lowest-energy excited-state configuration with the E , T_1 , and T_2 symmetry-adapted combinations of $\text{Cl}(p\pi)$ orbitals]. The energy differences between these states depend on electron–electron repulsion terms that are not explicitly treated in this chapter. The variations of these energies as the ligands or metals are altered are expected to follow patterns similar to those discussed above.

7.8.3 Ligand-to-Metal Charge-Transfer (LMCT) Band Shapes and Intensities

As noted in Tables 3 and 4, the LMCT absorption bands of transition metal complexes tend to be broad ($\Delta\nu_{1/2} \approx 5$ to $8 \times 10^3 \text{ cm}^{-1}$) and the molar absorptivities are large ($\epsilon_{\text{max}} \approx 1$ to $20 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$). Most of the bands are structureless in ambient solutions.

7.9 Metal-to-Ligand Charge-Transfer (MLCT) Absorption Band Energies

7.9.1 General Comments

MLCT excited states have been the subject of a vast amount of research and literature. This section will attempt a general overview of the area. More detailed accounts can be found elsewhere [45, 47, 100–102]. The overwhelming majority of the published studies involve low-valent metals with polypyridyl ligands. In fact, any ligand with relatively low-energy LUMO's will give rise to such transitions. The general features of these transitions are not different from the IPCT and LMCT transitions discussed above. Excited-state properties can be different when 1) The

electron is excited from a metal-centered nonbonding orbital (commonly a $d\pi$ orbital); and 2) The ligand-radical electron in the excited state is highly delocalized. Under such circumstances, the MLCT excited states are relatively undistorted (small λ_r), and the excited states can be long-lived under ambient conditions. As a result, they have attracted a great deal of attention. One or both of these features is usually absent in LMCT excited states, and most of these are relatively short-lived. Of course, there is a number of other properties that contribute to excited-state lifetimes and no universal generalizations are possible. Charge-transfer excited-state dynamics will be discussed briefly below.

7.9.2 Metal-to-Ligand Charge-Transfer (MLCT) Excited-State Energies

The same basic principles should be applicable to all CT transitions, and one expects Eqs. 7 and/or 9 to be at least as applicable for the MLCT absorption maxima as for the LMCT transitions. Many useful correlations of electrochemical potentials and $h\nu_{\max}$ have been found and exploited [9, 103–105]. The approaches outlined above will be used in this section.

Table 5 summarizes the MLCT spectra and electrochemical data of some simple $\text{Ru}(\text{bpy})_n(\text{Amine})_{(6-2n)}^{2+}$ complexes. There are two striking features of the MLCT spectra of these complexes: 1) The lowest-energy MLCT bands do not appear to have much of a reorganizational contribution; and 2) There are two MLCT transitions in these complexes. The first of these features is most evident in the similar values of $(h\nu_{\max} - F\Delta E_{1/2})$ in acetonitrile for the complexes with $n = 1$ and $n = 3$, despite the very large difference in the metal-centered reorganizational energies, χ_r , of these complexes (in water). The energies of the lowest energy MLCT bands of the complexes in Table 5 can be represented by Eq. 25.

$$h\nu_{\max} = F\Delta E_{1/2} + (1.3 \pm 0.2) \times 10^3 \text{ cm}^{-1} \quad (25)$$

This seems to suggest that reorganizational energies make very little contribution to $h\nu_{\max}$ for this class of complexes.

Table 5. Metal-to-ligand charge-transfer spectra: simple Ru^{II} bipyridine complexes.

Complex	MLCT ₁ ^{a,b}	MLCT ₂ ^{a,b}	χ_r^b	$E_{1/2}$, ^{a,c} V	$F\Delta E_{1/2}^b$

^c Vs. S.C.E. in CH_3CN .

The origin of the two MLCT transitions in these complexes has been recognized for some time [106, 107]. It is convenient to discuss this issue with reference to the $\text{Ru}(\text{NH}_3)_4\text{bpy}^{2+}$ complex. This complex has approximate C_{2v} symmetry, and its two MLCT bands arise from configurational mixing of the constituent pyridine moieties of the bpy ligand.

If the charge-transfer excited states of the pyridine moieties are represented by the zero-order wave functions Ψ°_{CT1} and Ψ°_{CT2} , then the resulting symmetric and anti-symmetric combinations are given in Eqs. 26a and b:

$$\Psi^\circ_{\text{CTs}} = (\Psi^\circ_{\text{CT1}} + \Psi^\circ_{\text{CT2}})/\sqrt{2} \quad (26a)$$

$$\Psi^\circ_{\text{CTa}} = (\Psi^\circ_{\text{CT1}} - \Psi^\circ_{\text{CT2}})/\sqrt{2} \quad (26b)$$

Of these two excited states, only the symmetric state, Ψ°_{CTs} , will mix with the symmetric ground state. Optical transitions to both states are allowed in C_{2v} symmetry. In the Hückel limit, the splitting between these two states can be represented as $2 H_{12}$, where H_{12} is the matrix element for mixing LUMOs of the two pyridines. The relative ordering of these states is not obvious. This leads to Eqs. 27 and 28 for the two transitions.

$$h\nu_l = E_{\text{pyCT}} - H_{12} + \dots \quad (27)$$

$$h\nu_u = E_{\text{pyCT}} + H_{12} + 2 H_{\text{gL}}^2/E_{\text{pyCT}} + \dots \quad (28)$$

These equations assume that only the lowest energy state mixes with the ground state, that the potential energy surfaces are harmonic and have the same force constants, and that the displacement of the ground state potential energy surface compensates for the stabilization and destabilization of the states that mix [116]. The use of electrochemical data in the evaluation of parameters that contribute to $h\nu_{\text{max}}$ leads to a significant correction term in strongly coupled donor-acceptor systems since the excited state species is not involved in the electrochemical processes [9, 116]. The optical and electrochemical processes are related by means of the electron-transfer equilibrium in Eq. 29.

This leads to Eq. 30 for the absorption maximum.

$$h\nu_{\text{max}} = F\Delta E^\circ + \chi_r^{\text{D/A}} + RT \ln K_{\text{DA}} + \dots \quad (30)$$

The contribution of the $RT \ln K_{\text{DA}}$ can be evaluated in terms of perturbation theory quantities mentioned above, and this leads to the experimentally useful expression in Eq. 31,

$$h\nu_{\text{max}} = F\Delta E_{1/2}^\circ + \chi_r^{\text{D/A}}(1 - 2\alpha_{\text{DA}}^2) + RT \ln K_{\text{el}} + \dots \quad (31)$$

where half-wave potentials have been substituted for standard potentials and K_{el} is

Figure 4. Qualitative illustration of the effects of configurational mixing in an A–D–A complex. a) Diabatic states with degenerate acceptors; b) Effect of mixing between the three states; it is assumed that only MLCT_1 mixes with the ground state.

a purely electrostatic term (roughly analogous to ion pair association constants) [116]. The meaning of the reorganization free energy is the same in equations 7 and 31; the argument summarized is an approach to the evaluation of γ_{DA} . This argument shows that apparent reorganizational parameters inferred from optical/electrochemical correlations are necessarily smaller than those required for a free energy correlation. The discrepancy increases with the fraction of charge delocalized as a result of donor-acceptor mixing (α_{DA}^2). When the optical/electrochemical correlations involve a comparison with constituent, thermal reorganizational parameters (as in Fig. 2 or implied in Fig. 3), then an additional correction for the fraction of charge delocalized is required and the effective “reorganizational energy” is $(h\nu_{\text{max}} - F\Delta E_{1/2}^{\text{D/A}}) \cong \chi_r^{\text{th}}(1 - 4\alpha_{\text{DA}}^2)$ [116].

In principle, this argument can be readily extended to the other bipyridine complexes in Table 5, since the energies of the two transitions would vary only in their contributions of λ_r and ϵ_s . When the electrochemical measurements are on the donor and acceptor of the covalently linked complex, as in Table 5, the success of optical electrochemical correlations appears to depend on the fortuitous cancellation of terms and the very small contributions of any variations in solvent contributions to the effective reorganizational energy. Since $\chi_r(\text{D})$ for the donor complexes considered here (Table 5) largely originates in the solvent, the negligible contribution of this quantity to the $\chi_r(\text{eff})$ for the MLCT transitions of bpy complexes is similar to the inferences about LMCT transitions in Section 7.8.1. This can be attributed to the very small dipole lengths of these transitions [31, 35].

For large differences in the energies of the ground and excited states, $h\nu_{\max} = (E_{\text{gL}} + \lambda_r) = (F\Delta E_{1/2} + \chi_p(1 - 2\alpha_{\text{gL}}^2))$, where $\epsilon_s = H_{\text{gL}}^2/E_{\text{MLCT}}^0 = H_{\text{gL}}^2/(F\Delta E_{1/2} + \chi_p)$, and the slope of a plot of $h\nu_{\max}$ vs $\Delta E_{1/2}$ is $F(1 - 2\alpha_{\text{gL}}^2)$. In practice, the variations of structural parameters that give rise to different values of $F\Delta E_{1/2}$ may also give rise to changes in χ_r . For the much studied Ru^{II} complexes, most of the contributions to χ_r arise from the solvent contributions (Table 2), and when the transition dipole length is small, as seems to be the case for polypyridyl ligands [31, 35], the variations arising from χ_r may be very small, as seems to be the case for the bipyridine ligand, and the slopes of such plots may be a measure of the electron density delocalized from the metal to the ligand (α_{gL}^2).

The above analysis raises the possibility that very different behavior, as in correlations of $h\nu_{\max}$ and $F\Delta E_{1/2}$, will be observed when the dipole length is long relative to the molecular dimensions, and/or when the effects of excited-state/excited-state (e. g., as manifested in H_{12}) configurational mixing differ greatly from the effects of excited-state/ground-state mixing (as manifested in ϵ_s in the above). The surprising result of the analysis presented here is that solvent contributions to χ_p are largely attenuated in strongly coupled systems. A perturbation-theory argument suggests that there is less attenuation of the effect of the donor and acceptor redox properties on the absorption energy. However, those properties must be evaluated in the actual complex.

7.9.3 Band Shapes and Intensities

The observed MLCT absorption bands are generally broad ($\Delta\nu_{1/2} \approx 4\text{--}6 \times 10^3 \text{ cm}^{-1}$, even for $d\pi/p\pi^*$ transitions). One would normally attribute this to an effect of the solvent reorganizational energy, as in Eq. 17. However, if the solvent reorganizational energy is as small as inferred in the preceding section, then these band widths are about twice those predicted. The implication is that the broad bands observed in fluid solution arise from the distribution of solvates and the effect of solvent on the transition energy (i. e., each differently solvated complex should have a different value of $F\Delta E_{1/2}$). This inference suggests that the evaluation of key parameters based on spectral fits to equations such as Eqs. 14, 15, 18, and 19 should be done with some caution.

7.10 Excited-State Lifetimes and Luminescence Properties

The $\text{Ru}(\text{bpy})_3^{2+}$ complex is a very good luminophore, and this and related complexes have been very extensively investigated [45, 101, 102, 108, 109]. The emission band shapes have generally been fitted to Eqs. 18, 19, or some variation of these [25, 37–39, 110]. The small solvent-reorganizational contributions, inferred above, suggest that the broad emission bands are not just a consequence of contributions of the solvent-reorganizational energy in these equations. The bandwidth is also likely

to show the effect of the distribution of solvates on the emission energy. On the other hand, some vibronic structure, arising from molecular vibrations with $h\nu_{\text{vib}} \gg k_{\text{B}}T$, is evident in the emission of the Ru^{II} polypyridyl complexes, as expected from Eqs. 18 and 19. The bandwidths of the resolved components may be more compatible with the above inferences.

A brief survey of some of the various observations on $\text{Ru}(\text{bpy})_3^{2+}$ are useful for perspective. It was noted above that $h\nu_{\text{max}}(\text{abs.}) \approx F\Delta E_{1/2}$ for this complex. It has also been reported that $[h\nu_{\text{max}}(\text{abs.}) - h\nu_{\text{max}}(\text{emission})] \approx 5 \times 10^3 \text{ cm}^{-1}$ for this complex [45, 101, 108, 109]. This energy should be approximately equal to $2\lambda_{\text{r}}$ plus the singlet/triplet MLCT excited-state energy difference, $E^{00}({}^1\text{MLCT}) - E^{00}({}^3\text{MLCT})$. Arguments presented above indicate that $h\nu_{\text{max}}(\text{abs.}) \cong (F\Delta E_{1/2} + \chi_{\rho})$ and $h\nu_{\text{max}}(\text{emission}) = [E^{00}({}^3\text{MLCT}) - H_{12}' - \lambda_{\text{r}}'] \cong (F\Delta E_{1/2} - \chi_{\rho})$. The heat generated during the Franck–Condon excited-state relaxation to the ${}^3\text{MLCT}$ state has been measured by photoacoustic-microcalorimetric methods [111, 112], and $E^{00}({}^3\text{MLCT})$ was determined to be $16.5 \pm 0.4 \times 10^3 \text{ cm}^{-1}$ in ambient aqueous solution. This is very close to $h\nu_{\text{max}}(\text{emission}) = 17.0 \times 10^3 \text{ cm}^{-1}$, observed in the same medium, and λ_{r}' (primed values for tripled state quantities) must be very small.

The relatively long excited-state lifetimes of $\text{Ru}(\text{bpy})_3^{2+}$ are readily attributed to a combination of the spin multiplicity changes that accompany relaxation, the large ground state–excited state energy difference and the small reorganizational energy that result in a relatively small nonradiative relaxation rate constant [45, 102]. In contrast, the intersystem crossing rate, from the Franck–Condon excited state to the ${}^3\text{MLCT}$ excited state is faster than the rate of vibrational relaxation within an electronic manifold, apparently a few hundred femtoseconds compared to a few picoseconds [48, 49]. Overall, it appears that the excited-state nonradiative relaxation rates depend very strongly on vibrational overlap, and a competition between state-to-state energy migration and vibrational relaxation.

7.11 Perspectives and Conclusions

This chapter has dealt largely with the information that may be obtained from the spectroscopy of charge-transfer excited states. It is an attempt to integrate several kinds of spectroscopic studies with electrochemical studies. This has led to the inference that solvent reorganizational energies often make very small contributions to the absorption (and probably emission) energies of very strongly coupled donor–acceptor complexes. This behavior limits the usefulness of standard electron-transfer formalisms in describing the energetics, band shapes, and so forth of such charge-transfer systems. In contrast, even strongly coupled donor/acceptor complexes still exhibit the electrochemical behavior characteristic of their constituent couples. Since solvation is a significant factor when electrode potentials are determined, the distribution of the solvates characteristic of the solution state will give rise to a distribution of electrode potentials and this is probably an important factor in absorption and emission bandwidths in solution.

“Pure” charge-transfer excited states are most rigorously defined in the weakly coupled limit. Simple examples of this limit are found in ion-pair complexes, complexes in which there is no covalent linkage between the donor and acceptor. Standard models work very well in this limit, and the IPCT absorption maximum is successfully described by the sum of the reduction potentials and the electron-transfer reorganizational energies of the constituent ionic partners, as in Eqs. 7 and 9 ($\gamma_{\text{DA}} \approx 0$).

When the donor and acceptor are covalently linked, the ionic contributions are no longer adequate to describe the observations. The effect of the covalent linkage can be symbolically represented by a parameter, γ_{DA} , that takes into account the changes in the parameters from their values at the ionic limit. To some degree, γ_{DA} can be linearized so that a set of modified parameters, designated in Eq. 9 as $E_{\text{a}}^{\circ}(\text{X}/\text{X}^-)$ and χ_{ρ}^{X} ($\text{X} = \text{D}, \text{A}$) can be defined for the covalently linked complex. When values of $E_{1/2}(\text{X}/\text{X}^-)$ can be directly measured in the strongly coupled complex of interest, they differ significantly from the purely ionic values. Values of χ_{ρ}^{X} can very rarely be directly measured in a covalently linked D/A complex, whereas the reorganizational parameter $\chi_{\text{r}}^{\text{X}}$ can be determined for the ionic limit from the measurement of self-exchange electron-transfer rates. The combination of the experimental correlation of $h\nu_{\text{max}}(\text{IPCT})$ with $h\nu_{\text{max}}(\text{LMCT})$ and a perturbation-theory argument for MLCT excited states demonstrates that solvent reorganizational contributions are far less in χ_{ρ}^{X} for the strongly coupled systems than in $\chi_{\text{r}}^{\text{X}}$ for the ionic limit. This appears to be a consequence of the very small dipole length for the charge-transfer transitions in covalently linked, strongly coupled D/A complexes.

8 Synthetic Applications of Photocatalytic Oxidation and Reduction Reactions of Organic Reactants on Irradiated Semiconductor Surfaces

Marye Anne Fox

8.1 Introduction

Developing efficient and broadly applicable methods for controlled oxidation and reduction reactions remains a significant challenge for synthetic chemists. Electro-synthesis is more and more frequently being considered as a reliable synthetic tool in the arsenal of techniques available to the synthetic organic chemist. As a consequence of the utility of conventional electrochemistry, the related field of photo-electrochemistry has also become more interesting as a means for inducing redox reactions as a solution to problems in organic synthesis. Photoelectrochemical synthesis, like typical electrochemical transformations conducted in a standard electrochemical cell, provides a means for controlling reactivity from three venues: selective adsorption for chemoselective activation of a desired substrate, potential control for selective thermodynamic activation of one oxidant or reductant in the presence of others, and current control for producing a product at the desired oxidation level [1, 2].

One particularly appealing route for effecting controlled redox reactions involves an array of surface-mediated reactions initiated by ultraviolet irradiation of suspended semiconductor particles [3–13]. Such reactions involve band-gap excitation of the semiconductor, interfacial electron transfer, and secondary dark chemical reactions of singly oxidized and reduced adsorbates. Because the semiconductor surface is restored to its original structure and oxidation level after these transformations, these photoreactions are often called photocatalytic, leaving the light-responsive photocatalyst ready to act as initiator for another cycle. The use of such photocatalysts also obviates the need to acquire expensive electrochemical equipment.

This exciting area has been studied extensively over the last two and a half decades, primarily because of its potential as a route for solar energy conversion by production of chemical fuels [8–13] and as a means for environmental detoxification of polluted air or water streams [14–21]. Solar energy conversion by the

photocatalytic splitting of water (to its component elements hydrogen and oxygen) has been a particularly appealing goal of this research, because it represents a conceptually simple route to a combustible gas, hydrogen, which can be easily burned back to water via a highly exothermic and pollution-free reaction. Indeed, photocatalytic water splitting represents one of the “Holy Grails” of current chemistry [22]. Equally appealing, a solar-driven route for the complete mineralization of potentially toxic organic materials to simple inorganic, nontoxic compounds and salts would be a significant and important chemical achievement [23].

Although the most thoroughly investigated photoelectrochemical investigations have focused on changes in oxidation state in simple inorganic molecules (e.g., in water splitting, carbon dioxide or nitrogen reduction, or metal deposition from ionic salts), the principles developed in these studies are equally applicable to organic transformations. Photocatalytic water splitting [10–14] and advanced oxidation processes for photodetoxification [15–21] also rely on the same sequences: namely, photochemical production of an electron/hole pair, followed by interfacial photoinduced electron transfer, effecting redox half reactions on the surface of a suspended semiconductor. The oxidized and reduced species thus produced can then participate in a wide array of subsequent dark chemical transformations, and the extent to which the surface affects the course of subsequent dark reactions will dictate the feasibility of this technique in achieving synthetically useful redox transformations of organic adsorbates, at least in competition with complete oxidative mineralization of the adsorbate in question.

A specific aim of this chapter is to compare the similarities and differences in reactivity that distinguish photoelectrochemical conversions from those that take place on poised electrodes or upon treatment with homogeneously dispersed redox reagents. In this chapter, therefore, we consider specifically how reactions that take place under controlled ultraviolet irradiation on a redox-active heterogeneous suspension permit specific chemical selectivity and control of oxidation and reduction level.

Because photocatalytic redox events are driven by light, efficient interfacial electron transfer to produce singly oxidized radical ions always competes with energy-wasting electron-hole recombination. Thus, back electron transfer between the oxidized and reduced radical ion pair formed on the irradiated surface competes with diffusion of the redox intermediates from the surface into the bulk of the contacting solution and with trapping of the surface-bound radical ions by trapping reagents. The semiconductor surface itself can also influence the stability of the radical ion pair generated, producing a quite different reactivity from that observed when the same intermediates are produced in homogeneous solution. The efficiency of electron-hole recombination is an inherent limitation for practical applications of photocatalysis in synthesis, as the high drive force always makes charge recombination favorable, thus limiting the quantum efficiency of the desired reaction.

Photoelectrochemistry is inherently interdisciplinary, and it has attracted the attention of chemists who approach the various aspects of the science from quite different perspectives. Although the diversity of this approach reflects the importance of the field, it does also make it virtually impossible to include all relevant work in a summary chapter of reasonable length. Even so, the examples cited here can serve,

we believe, as a helpful introduction to those new to this field. Each year the compilation of reactions that can be initiated by photoelectrochemical activation on irradiated semiconductors grows, and a comprehensive discussion of all relevant work becomes impossible. For that reason, examples from our own research group are usually chosen as illustrative of the principle being discussed [1–7, 24, 25]. We acknowledge at the onset that this article therefore neglects many important contributions to the area, simply in the interest of maintaining a review of reasonable length that covers the principles most relevant to synthetically useful transformations. For more complete coverage, we refer the interested reader to a number of earlier reviews that present more detail about mechanisms of these, and related, conversions, and for which this treatment represents an update.

The emphasis of this article is on organic transformations, and the principles chosen here for illustration of the operative examples are chosen from organic chemistry. In illustrating these principles, we provide a compilation of many controlled redox reactions of a range of organic functional groups. In describing the guiding principles of synthetic photoelectrochemical conversions on illuminated surfaces of metal oxide and metal chalcogenide semiconductors, we show how photoelectrochemical catalysts are useful as selective activators of organic reactivity. We describe here illustrations of photocatalytic oxidations, reductions, and pericyclic reactions of a wide range of organic substrates.

8.2 Principles Governing Photoelectrochemistry

Organic photoelectrochemistry can be defined as a field in which redox reactions of carbon-based compounds are initiated or assisted by the absorption of a photon at the surface of a semiconductor particle to which the substrate of interest is adsorbed. In a photoelectrochemical conversion, the organic substrate of interest is not converted to an excited state, the activating photon having been absorbed instead by the semiconductor.

8.2.1 Redox Reactions on Irradiated Semiconductor Surfaces

By definition, a semiconductor does not have a continuum of states (as do metallic conductors) but rather a band structure. The filled levels, called the valence band, are an energetically closely spaced array of orbitals composed of the valence electrons of the material. A gap exists between the top edge of this band and the lower edge of a similar closely spaced array of orbitals that are unoccupied in the ground state, that is, the conduction band. The gap separating these bands is called the band gap.

In an intrinsic (undoped) semiconductor, the Fermi level lies at a potential exactly halfway between the bands, whereas with an *n*-type (negatively doped) or a *p*-type (positively doped) semiconductor, the Fermi level respectively lies just below the conduction band edge or just above the valence band (Figure 1).

Figure 1. Band bending in *n*- and *p*-doped semiconductors. (The vertical line represents the interface between the solid semiconductor on the left and a contacting liquid on the right.)

When a semiconductor surface is brought into contact with an electrolyte containing a redox couple, interfacial electron transfer can transpire, to equilibrate the solution phase potential and the Fermi level of the bulk semiconductor. As electron exchange takes place across the interface, equilibration with the solution occurs and the bulk Fermi level moves to the solution-phase equilibrium potential, whereas the band-edge positions at the surface remain fixed at their original values. Thus, in moving inward from the semiconductor–electrolyte interface, the bands bend. Charge injection in this region of bent bands forces electrons to move in the opposite direction from holes: in an *n*-doped material, electrons move away from the surface and toward the bulk of the semiconductor while the holes move toward the surface. Thus, band bending assists in improving the efficiency of photoinduced charge separation.

As a result of band bending, the surface of an irradiated *n*-type semiconductor becomes electron-deficient and acts as a photoanode toward an oxidizable adsorbate. The conduction-band electron in an irradiated semiconductor is almost isoenergetic with the reduction potential for oxygen. In aerated solutions in which the semiconductor is saturated with adsorbed oxygen, the electron can often be trapped as superoxide, or when bound to the surface of the photocatalyst, it can trap other surface-confined reactive intermediates [26, 27].

When a semiconductor surface (whether configured as a single-crystal electrode or as a particle) is exposed to light of an energy greater than the band gap, a band-to-band transition takes place, which moves an electron from the filled valence band to the vacant conduction band (Figure 2). Every semiconductor therefore has a wavelength onset that represents an energy minimum characteristic of that particular material. The absorption of a photon thus induces charge separation, generating a highly energetic electron and creating a lower-energy vacancy in the valence band. This charge-separated species is referred to as an electron-hole pair.

Back electron transfer (recombination of the electron-hole pair) is, of course, highly favorable from a thermodynamic viewpoint. But because of the absence of states in the semiconductor band gap, quantum restrictions slow recombination by back electron transfer and the lifetime of the photogenerated electron-hole pair is sufficiently long to permit charge trapping. Thus, a valence-band hole is trapped for some period and can, at least in principle, act as an anode poised at the energy of

Figure 2. Photoexcitation of an *n*-type semiconductor particle.

the valence-band edge. The conduction-band electron can, in principle, act similarly, as a cathode poised at the band edge of the conduction band. Thus, we can think of the excited semiconductor surface as presenting an electron-hole pair to an adsorbed substrate or to a contacting solution including a redox-active reagent, with the charge carriers localized in the conduction and valence bands, respectively. In an *n*-type semiconductor, the surface of the semiconductor becomes electron-deficient and acts as an oxidative site toward an oxidizable organic compound. If an adsorbed reagent of the correct redox potential can trap one of the charge carriers faster than the electron and hole can recombine, new surface-mediated chemistry will be observed.

Thus, on a semiconductor, it is possible for the conduction-band electron to be captured by interfacial electron transfer to an appropriate adsorbed acceptor and for the valence-band hole to be filled by interfacial electron transfer from an adsorbed organic donor, at a rate competitive with spontaneous back electron transfer from the charge-separated pair (Figure 3).

When the valence-band hole and the conduction-band electron are both trapped by an appropriate oxidation or reduction half reaction, singly oxidized and reduced species are formed on the surface of the photocatalyst. Because these adsorbed intermediates can move about the surface, either migrating closer together or diffusing away from each other, before back-electron transfer occurs, novel chemistry is likely to ensue. It is a unique characteristic of photoelectrochemical catalysts that both oxidized and reduced species are produced on the same surface. As a result,

Figure 3. Interfacial electron transfer with an adsorbed electron donor D and acceptor A. (The vertical line represents the interface between the solid semiconductor on the left and a contacting liquid on the right; the horizontal lines represent the respective redox potentials of A and D.)

Figure 4. Charge trapping on a metalized semiconductor powder, as an analog to a short-circuited electrochemical cell.

photoelectrochemical redox reactions often differ significantly from the electrochemical transformations observed in a conventional three-electrode cell, where the surface of the working electrode is rendered either oxidizing or reducing by virtue of an imposed potential. That is, unlike in photocatalysis, the oxidizing and reducing sites are appreciably physically separated in a standard electrochemical conversion, even occurring in separate half cells in which the anode and cathode are in separate compartments divided by a membrane. In the latter arrangement, secondary reactions between the singly oxidized and reduced intermediates are unlikely.

Apart from the lack of physical separation of the anode and cathode, a suspended semiconductor particle can itself be considered to be a nanoscopic version of a miniature electrochemical cell [8–10, 28]. In photocatalysis, both the anodic and cathodic sites are produced on the same particle, whose dimensions can vary from the subcolloidal to single crystalline in size. This variation permits photocatalytic redox transformations to be performed without the standard electrochemical equipment usually employed for maintaining the potential or analyzing current flow during an electrochemical conversion. Bard [8] has shown that, for practical applications, the semiconductor photocatalyst can be considered as a “short-circuited” electrochemical cell, prepared by deposition of an inert metal with low overpotential onto the surface of the semiconductor. Such a metalized powder is shown in Figure 4. This powder thus includes regions for both photoactivated oxidation of an organic substrate adsorbed at the irradiated semiconductor–electrolyte interface and for collection of the photogenerated electrons as a pool on the metal site. As in a standard electrochemical cell, these metalized powders include sites for photo-induced oxidation and reduction, analogous to the working anode and cathode. On platinized TiO_2 powders, however, no external current flow accompanies these transformations.

Even without deposition of a metal island, wide band-gap semiconductor powders often maintain photoactivity, as long as the rates or the positions of the oxidative and reductive half reactions can be separated. Photoelectrochemical conversion on untreated surfaces also remains efficient if either the oxidation or reduction half reaction can take place readily on the dark semiconductor upon application of an appropriate potential. Metalization of the semiconductor photocatalyst will be essential for some redox couples, whereas, for others, platinization will have nearly no effect. Furthermore, because the oxidation and reduction sites on an irradiated particle are very close to each other, secondary chemical reactions can often occur readily, as the oxidized and reduced species migrate toward each other, leading either to interesting net reactions or, unfortunately, sometimes to undesired side reactions.

For photoelectrochemical conversions to proceed on untreated surfaces, either the oxidation or reduction must occur readily in the dark, thus scavenging one of the photogenerated charge carriers. That is, there must be a kinetic preference for either oxidation or reduction. An alternative explanation for the effectiveness of native powders may be the involvement of defect sites, which can act as charge accumulation centers in parallel to purposely introduced metal sites.

Obviously these powders are simpler to work with than a full electrochemical cell, in that they are easily moved and inexpensive, and do not require extensive electrochemical analytical instrumentation. Furthermore, depending on particle size, the complete development of a space-charge region at the interface of such a powder may be absent. In these films, charge separation is governed by the kinetics at the film surface, not by the electric field of the space-charge layer [8, 29].

If one conceptually considers making the particle smaller and smaller, one eventually reaches a colloidal state. Colloidal forms of metal oxide semiconductors can often be prepared by hydrolysis of an appropriate organometallic precursor, and the resulting suspension may represent the ultimate miniature photoelectrochemical cell [28]. The resulting colloid can then be used as synthesized or it can be deposited as a thin film on an inert support.

This analogy to a short-circuited electrochemical cell also explains why photoactivity is maintained as the size of the photocatalyst decreases from a single crystal or powder to the colloidal range, even if physical properties of the photocatalyst are changed. For example, the absorption characteristics, the quantum efficiency of charge separation, and the kinetics of interfacial electron transfer are often influenced by the photocatalyst particle size. On sufficiently small particles, the space-charge width needed for effective band bending may exceed the dimensions of the particle, making charge separation much less efficient. Even in this case, though, surface effects are often still observed.

When molecules or intermediates are adsorbed onto a specific surface, the conformational equilibrium can be altered from that observed in solution, because surfaces can transmit electrostatic forces to stretch bonds in the adsorbate. This, in turn, affects the relative rates of intra- and intermolecular reactivity, both in unimolecular rearrangements and in collisional transformations.

8.2.2 Comparison of a Photoelectrochemically Generated Electron-Hole Pair and a Molecular Excited State

The electron-hole pair produced by irradiation of a suspended *n*-type semiconductor particle is similar in some ways to an excited state of an organic compound. In a typical organic molecule, there is a large gap between the filled and vacant molecular orbitals, typically so large that most organic solids are insulating. Promotion of an electron from the highest occupied molecular orbital (HOMO) to the lowest-lying unoccupied molecular orbital (LUMO) by absorption of a photon in an organic ground state alters the net oxidation and reduction potentials. That is, removing or adding an electron from/to the excited state is much easier than from/to the corresponding ground state, because the promoted electron occupies a higher-

Figure 5. Comparison of a molecular excited state with a semiconductor electron-hole pair.

energy orbital and can be more easily removed because of the vacancy created in a lower-lying orbital that is normally filled in the ground state. The higher electron-transfer activity of most excited molecules thus derives from an enhanced electron affinity (from a vacancy in the HOMO) and a reduced ionization potential (from the high energy of the electron in the LUMO). Figure 5 shows the similarity of an excited state to a photogenerated electron-hole pair produced by irradiation of a semiconductor powder.

Relaxation of the highly energetic electron from the LUMO to the vacancy created in the HOMO regenerates the ground state, just as back electron transfer within the electron-hole pair restores the photocatalyst to its original state. Because charge recombination is so favorable energetically, the electron-hole pair typically lives only a few hundred picoseconds or less. In comparison, some excited states, depending on whether their multiplicity is singlet or triplet, can live for much longer periods, up to several microseconds in some cases. Thus, with either a surface-confined electron-hole pair or an excited state, subsequent chemical or electron-transfer events must be very fast to compete with relaxation to the ground state. These difficulties cause a reduction in quantum efficiency both in inducing chemical trapping of the electron-hole pair or in observing net chemical conversions from an excited organic molecule. This lower quantum yield is a practical limitation on the synthetic utility of either conversion, particularly if an undesired side reaction competes with the desired transformation.

8.2.3 Energy Considerations

The fixed potential of the band edges of a given semiconductor can be established independently by many physical or electrochemical methods. These band-edge positions define the limits of the attainable oxidation and reduction half reactions that can be achieved on this surface. As long as the oxidation potential of the adsorbed donor (hole trap) is lower than the valence band edge, and the reduction potential of the adsorbed acceptor (electron trap) is lower than the conduction-band edge,

Table 1. Band positions^a in some common semiconductors [30].

Semiconductor	E_{VB} (V, vs SCE)	E_{CB} (V, vs SCE)	E_g (V)	$A(E_g)$, (nm)
TiO ₂	3.0	0.0	3.0	410
SnO ₂	3.8	+0.3	3.5	350
ZnO	2.9	-0.1	3.0	410
SrTiO ₃	3.0	-0.2	3.2	390
CdS	2.2	-0.2	2.4	520
CdSe	1.4	-0.3	1.7	730
CdTe	1.4	0.0	1.4	890
GaAs	0.8	-0.6	1.4	890
GaP	1.4	-0.9	2.3	540
InP	1.2	-0.1	1.3	950

^a Approximate positions. Source: Ref. [5]. In water at pH 1.

electron transfer at the illuminated interface is thermodynamically favored, Figure 3. Although the band gap (E_g) in the semiconductor photocatalyst is subject to shifts with pH, solvent, and temperature, the corresponding onset wavelengths dictate the accessible energy for the trapped electron or hole. Thus, the valence-band edge (E_{VB}) represents a thermodynamic limit for the oxidation potential of the adsorbate of interest, whereas the conduction band edge (E_{CB}) represents the corresponding limit for the reduction half reaction.

Table 1 provides a list of these values for the most commonly accessible semiconductor powders suspended in aqueous acid, along with a conversion of the band gap to an absorption onset wavelength $A(E_g)$. The band-edge positions [30] can also be adjusted by control of the particle size of the irradiated semiconductor. Quantization effects can shift these values by more than 100 nm; this allows control of the onset wavelength and of the band positions of several common semiconductors.

By carefully choosing the semiconductor, one can select the onset wavelength over a range varying from the long-wavelength ultraviolet (UV) through the visible region. One can also define the available redox potentials accessed on that semiconductor. Single-electron transfer from an adsorbed donor can be expected to compete favorably with electron-hole recombination for any adsorbate whose oxidation potential is lower than the valence-band edge, and the corresponding single-electron transfer to an adsorbed acceptor whose reduction potential is lower than the conduction band edge is similarly exothermic.

A comparison of typical redox potentials for common organic functional groups with the valence band edge of TiO₂ reveals that many organic molecules and species can function exothermically as electron donors to a surface-bound photogenerated hole [5]. Because of the high positive valence-band edges in metal oxide semiconductors, many oxidative conversions can be conducted on aerated solutions in which the irradiated TiO₂ photocatalyst is suspended. Indeed, the high oxidizing power implied by the band edge (3.0 V vs SCE) permits single-electron oxidation of

virtually any organic substrate that contains either nonbonding electrons or a conjugated π system.

8.2.4 Solvent Effects

Because of the high photooxidative reactivity of TiO_2 , deriving from the high positive potential of a valence-band hole, even water can be oxidized on irradiated TiO_2 . In aqueous solutions, therefore, direct oxidation of an adsorbed substrate must compete with solvent oxidation [31]. The formation of hydroxyl radicals by single-electron oxidation of surface-bound water is usually the dominant process in water, with the radical having been detected by EPR spectroscopy [32–34] and implicated by isotope effects [35].

The hydroxyl radical is highly reactive toward many organic reactants, and high yields of oxidation and oxygenation products are often obtained in water. The high reactivity of $\cdot\text{OH}$ has a drawback, however, if the desired goal is controlled redox reactivity with synthetic utility, in that little selectivity or reaction control is possible for reactions initiated by a radical that is so active. Furthermore, if the organic substrate of interest is rather nonpolar, it is difficult to control the level of photo-induced oxidation. It effectively increases the adsorptivity of that product so that the partially oxidized substrate does not diffuse away from the irradiated surface. If the organic reactant is hydroxylated in the photocatalyzed surface-mediated reaction with a hydroxyl radical, further secondary oxidations are accelerated because the adsorptivity of the initial product is greater than that of the reactant.

Overoxidation, sometimes to the point of complete mineralization, is often observed in water. Of course, this complete destruction of organic materials is useful if the goal is a photocatalytic conversion that results in purification of a water stream, but for selective organic redox chemistry of use to the synthetic organic chemist, this lack of control can be disastrous.

By shift from a reactive solvent (e.g., water) to an inert solvent (e.g., acetonitrile), this problem can be easily solved. Acetonitrile is oxidized just outside the potential window of the band gap of common semiconductors, so the adsorbed substrate can be selectively oxidized. Without an oxidative source for producing hydroxyl radicals, however, there are fewer opportunities for the incorporation of OH groups.

In nonaqueous solvents, the band edges shift slightly from those seen in water at pH 1. In particular, the conduction band becomes sufficiently negative to cause reduction of oxygen, so that interfacial electron transfer to capture the photo-generated electron-hole pair generates an organic cation radical and a superoxide on the same surface. When these intermediates are formed at nearby sites, controlled new reactions can be observed. Therefore, most photoelectrochemical reactions that are of interest for their synthetic utility are attained by irradiation of metal oxide semiconductor suspensions (often TiO_2) in the presence of air while suspended in an inert solvent, often acetonitrile. Photocatalytic reactivity can be partially controlled, in fact, by the use of mixed solvents to control surface polarity [36].

8.2.5 Semiconductor Stability toward Catalytic Cycling

The utility of visible- or UV-sensitive semiconductors as initiators for redox chemistry is limited by the instability of the surface under irradiation while in contact with an oxidizable substrate or an electrolyte. This decreased activity is caused by the chemical reactivity of the semiconductor itself, so that an insulating (blocking) layer is formed or the electrode quickly corrodes. This lack of stability is particularly troublesome with small-band-gap semiconductors that adsorb strongly in the visible region.

Much attention has been devoted to solving this problem by the attachment of catalysts or inert conductive layers on the surface, by the chemical alteration of the surface composition of the semiconductor (e.g., by silicide formation), by change of the composition of the electrolyte, or by imbedding of the semiconductor in a protective layer or film. In principle, the modification of electrodes, powders, and films by chemical attachment of photoactive or electroactive catalysts [37, 38] could address these difficulties. By attaching a chemical catalyst, one can competitively improve the operational lifetime of a given semiconductor by suppressing photocorrosion and improving the rate of a desired redox reaction. Although the use of nonaqueous solvents can prolong the lifetime of II/VI and III/V semiconductors like CdS or GaAs, most non-oxidic semiconductors, especially those with narrow band gaps, which are thus responsive to visible light, quickly degrade upon exposure to light, and others even react with the organic materials in the dark.

For these reasons, most photoelectrochemical studies of organic transformations, have employed robust, highly stable metal oxides as the photosensitive surface. Metal oxides are often used for photocatalysis, since they withstand decomposition under most photoelectrochemical conditions, with TiO_2 , ZnO , and SnO_2 most frequently used for these applications. Nanocrystalline porous TiO_2 has such a large internal surface area that efficient light absorptivity and high reactivity are often attained [39]. Bicomponent metal oxides, such as WO_3/TiO_2 are also useful photooxidation catalysts [40, 41], and significant enhancement of redox activity has been observed in several large-and-small band gap composites [42, 43]. Unfortunately, these metal oxides possess large band gaps, making them responsive only to ultraviolet irradiation and, hence, less useful for solar energy conversion than their highly colored, but chemically unstable, narrow band-gap relatives are.

8.2.6 Photosensitization

Adsorption of dyes onto a semiconductor surface allows for another mode of photoactivation [44–48]. The dye adsorbs a photon, generating an excited state in which a sufficiently higher-energy orbital is populated to allow direct injection of an electron into the conduction band edge [1]. The dye thus becomes oxidized and can either react chemically with nucleophiles by bond formation or can be restored to its original oxidation level by electron transfer. In the latter case, the reaction partner is oxidized, regenerating the ground state of the sensitizer ready to participate in

Figure 6. Oxidative electron exchange at a dye-sensitized *n*-type semiconductor electrode between the excited state of the sensitizer *S* and an adsorbed donor *D*.

another sensitization cycle and initiating permanent oxidative consumption of the donor. With dye sensitization, charge separation and oxidation of the immediately accessible donor takes place in the same manner as would have been attained by direct excitation of the semiconductor, followed by interfacial electron transfer from an adsorbed donor. (Compare Figures 3 and 6).

8.3 Mechanism

These arguments suggest that organic oxidations should be particularly facile on UV-irradiated TiO₂ powders suspended in CH₃CN [49]. To illustrate key mechanistic features, we will look in some detail at the oxidation of 1,1-diphenylethylene as a typical example of a photoinduced oxygenation. The products observed in this conversion are benzophenone and CO₂, Eq. 1 [50].

The thermodynamic considerations discussed earlier suggest that irradiation of a TiO₂ suspension gives rise to an electron-hole pair, with the valence-band edge at about +3.0 V vs SCE and the conduction band edge at about −0.8 V. Since the oxidation potential of 1,1-diphenylethylene is +1.8 V in acetonitrile, formation of its radical cation should be thermodynamically permissible on illuminated TiO₂. Interfacial electron transfer from an adsorbed olefin and adsorbed oxygen should thus generate an olefin cation radical and superoxide (Figure 7).

The high chemical yield of the oxidative cleavage product argues for efficient interception of a cation radical (Eq. 2), perhaps by superoxide produced by surface trapping of the conduction band electron.

Figure 7. Trapping of the electron-hole pair to produce a cation radical and superoxide.

If so, one may expect products to result from chemical bond formation between the cation-radical-anion-radical pair, which are both paramagnetic and of opposite charge. In the latter route, there is a precedent for the formation of dioxetane intermediates of stable olefin cation radicals [51], as in the characterization by Nelsen and coworkers of a dioxetane cation radical from adamantylidene cation radical [52]. If a dioxetane is formed, either in neutral form or as a cation radical, the TiO_2 surface can function in an additional role, that is, as a Lewis acid catalyst, to induce decomposition of the dioxetane. Since no chemiluminescence could be observed in these reactions, apparently Lewis acid catalysis provides a nonradiative route for cleavage of this high-energy intermediate. That TiO_2 can indeed function in this way can be demonstrated by independent synthesis of the dioxetane derived from 1,1-diphenylethylene, which does indeed decompose to benzophenone when it is stirred in the dark on titanium dioxide.

A Hammett plot (a linear free-energy relationship) of the relative rate of oxidative cleavage of para-substituted diphenylethylenes against the σ^+ value of each substituent was indeed linear with a negative slope, consistent with the localization of positive charge in the transition state for the oxidation. Similarly, competition experiments involving mixtures of these same *p*-substituted diphenylethylenes, for which surface-adsorption equilibria can be assumed to be equivalent, showed the expected order of reactivity, consistent with formation of an intermediate involving the development of positive charge [53], that is, the more electron-donating substituent stabilized the cation radical intermediate and assisted in its formation by reducing the oxidation potential of the substituted reagent.

trans-Stilbene is a species that should also be exothermically oxidized by a TiO_2 valence-band hole. Indeed, direct observation of a transient radical cation from *trans*-stilbene was made when colloidal TiO_2 suspended in acetonitrile containing *trans*-stilbene was excited with a laser pulse. The observed transient was identical in absorption maximum and in lifetime to that obtained when an authentic sample of the stilbene cation radical was produced in the same medium by pulse radiolysis [54, 55]. This experiment does not necessarily prove that the cation radical is the critical intermediate in the transformation, but, since it requires the extrapolation of similar photochemical reactivity to colloids and powders, it does demonstrate that single-electron transfer can be induced by photoexcitation of the semiconductor.

Furthermore, the transient formation of cation radicals can be observed when a colloidal titanium dioxide suspension is flashed in the presence of an olefin [56]. The flash photolysis experiments also show that the surface influences the subsequent chemistry of the photogenerated intermediate. In fact, oxygenation and isomerization dominated the chemistry observed for *trans*-stilbene, with the same product distribution obtained upon starting with either the *cis* or the *trans* isomer (Eq. 3).

However, no cyclization products could be observed, in contrast to the results observed with the *cis*-stilbene cation radical produced in homogeneous solution.

A different mechanistic possibility (from the recombination of the cation radical with superoxide) is that the organic cation radical formed by oxidative capture of the photogenerated hole at the irradiated surface could be trapped by co-adsorbed triplet oxygen (Eq. 4).

Oxygenation products would likely be formed, and it is difficult, indeed, to exclude this route, given the high concentration of adsorbed oxygen present on the photocatalyst's surface. The formation of oxidative cleavage product would at some stage require either back electron transfer from a surface-bound reduced species or direct trapping of a conduction-band electron by the oxygenated cation radical.

Superoxide (O_2^-), the expected side product produced by trapping a conduction band electron, is itself highly reactive, and we also should consider whether an alternative mechanism (superoxide + neutral DPE) might account for the observed products. However, control experiments show that superoxide solubilized in acetonitrile is unreactive toward 1,1-diphenylethylene in the dark [50]. Furthermore, added superoxide scavengers are ineffective at inhibiting the oxidative cleavage of DPE. Thus, if superoxide is formed, it never escapes from the irradiated surface. Rather, it must intercept singly oxidized intermediates generated on the irradiated semiconductor.

Back electron transfer between the olefin cation radical and superoxide would also be thermodynamically favored and would decrease the efficiency of the photochemical oxidative cleavage. It is also possible that, because spin restrictions are relaxed within the radical ion pair, the recombination could potentially generate singlet oxygen. Were it formed in this way, singlet oxygen would indeed oxidize 1,1-diphenylethylene to benzophenone. However, there is no evidence for the involvement of singlet oxygen as a general route, since the chemistry of singlet oxygen differs significantly from that observed on irradiated semiconductors. Tetramethylethylene, for example, reacts with singlet oxygen in homogeneous solution by a

clean ene reaction, giving an allylic hydroperoxide as a major product [57]; however, when the same reagent is activated photocatalytically by irradiation of titanium dioxide in the presence of tetramethylethylene, a complex mixture is produced in which oxidative cleavage is the main pathway. Foote and coworkers have shown that singlet oxygen is unreactive toward *trans*-stilbene, unless electron-transfer pathways are involved [58]. Thus, if singlet oxygen is ever formed by reversible electron transfer on an irradiated semiconductor surface, its subsequent chemistry differs significantly from that observed in solution.

Because radical ions are known to react through a number of possible reaction pathways, [59], photoelectrochemistry provides, in principle, a possible method for choosing among competitive routes. The formation of a cation radical by hole trapping by an organic donor on an irradiated semiconductor surface often gives rise to products different from those obtained on a poised metal electrode or those derived from the same cation radical when produced in homogeneous solution (Eq. 5) [60].

Thus, the photocatalyst not only generates the radical ion but also controls its subsequent chemistry.

The selection of one preferred route for dark secondary reactions from photogenerated cation radicals can also be seen in the products derived from 1-methylnaphthalene. Although ring cleavage is observed on irradiated TiO_2 suspensions, side-chain oxidation of the corresponding radical cation takes place in homogeneous solution (Eq. 6) [61].

We conclude that photocatalysis on irradiated metal oxide surfaces is initiated by interfacial single-electron transfer to capture the photogenerated hole in a likely first step in oxidative photocatalysis. This route produces an olefin cation radical when an alkene is the substrate of interest. This species is then trapped by adsorbed oxygen, producing a strained intermediate that is opened and cleaved under the Lewis acidic conditions operative on the surface of TiO_2 . Analogous single-electron oxidations are also likely as the first step in other organic conversions observed on TiO_2 , as we will see in the following sections.

8.4 Chemical Selectivity through Photoelectrochemical Activation

In principle, like all electrochemical reactions initiated by the transfer of an electron across an electrode–electrolyte interface, photoelectrochemical transformations offer the possibility of more precise control than can be attained with reactions that take place in homogeneous solution [62, 63]. This better selectivity derives from three features associated with reactions that take place on surfaces, and hence with the photoelectrochemical event: the applied potential (allowing for specific activation of a functional group whose oxidation potential is higher, even in a multifunctional molecule); the chemical nature of the electrode surface (and hence of the adsorption equilibrium constant of a specific molecule present in the double layer); and, finally, control of current flow (and hence a constraint on the number of electrons passed to an adsorbed reactant).

8.4.1 Adsorption and Surface Effects

Preadsorption of an active substrate has been shown from kinetic studies to be necessary for efficient photoelectrochemical activation. The factors that influence the binding constant for a substrate of interest adsorbed on the surface of metal oxide semiconductors can be quite complex. Proton exchange can take place readily at the acidic and basic sites that exist on TiO_2 [64, 65] and even without proton exchange and electrostatic effects, strong hydrogen-bonding interactions can also influence these equilibria. [66–68] Charge-transfer interactions [64, 69] have also been suggested as significant influences on adsorption equilibria. Even substrates lacking polar or ionizable groups, for example, saturated hydrocarbons, have been observed to bind to oxide surfaces, through nonspecific dispersion forces [64].

Because adsorption equilibria can produce a substantially different population at the semiconductor–liquid interface than is present in solution, interfacial charge trapping can produce specific activation of the better adsorbate from a mixture. Thus adsorption pre-equilibria are likely to be important in controlling the relative rates of photooxidation of competing substrates on semiconductor surfaces. Because adsorption equilibria can be influenced by the addition of very small amounts of co-solvent additives, higher reactivity [36] and higher selectivity can often be simulta-

neously observed in the oxidation of a more strongly adsorbed site over a less strongly adsorbed one. This preference can even be observed for preferential adsorption sites within a single molecule, for example, a 7:1 preference for oxidation of the primary site over the secondary site is observed in the photocatalytic oxidation of 1,4-pentanediol on illuminated TiO_2 (Eq. 7) [65].

Most reactions on surfaces are complicated by variations in mass transfer and adsorption equilibrium [70]. It is precisely these complexities, however, that afford an additional means of control in electrochemical or photoelectrochemical transformations. Not only does the surface assemble a nonstatistical distribution of reagents compared with the solution composition, but it also generally influences both the rates and course of chemical reactions [71–73]. These effects are particularly evident with photoactivated surfaces: the intrinsic lifetimes of both excited states and photogenerated transients and the rates of bimolecular diffusion are particularly sensitive to the special environment afforded by a solid surface. Consequently, the understanding of surface effects is very important for applications that depend on chemical selectivity in photoelectrochemical transformation.

First, it is important to recognize that the chemical character of a surface, even for those faces that are not photosensitive, can change the rates and reaction paths of chemical reactions taking place thereon [74]. The effect of the surface on the diffusional motion of adsorbates, whether they are stable species or reactive intermediates, depends sensitively on the adsorptive forces that bind the reagent to the reaction site. When a substrate of interest is adsorbed, surface confinement changes the electronic distribution in the molecule and, hence, both the accessible trajectories for interaction with another reagent and the molecule's electron density.

Even the underlying support can influence relative reaction rates [75]. For example, when a photochemical precursor to a family of benzylic radicals, for example, benzyl phenylacetate, a dibenzyl ketone, or a dibenzyl sulfone, is irradiated while adsorbed on dry silica gel [76], spectroscopic measurements can demonstrate that singlet and triplet radical pairs are produced. The details of reactions taking place through radical recombination show that local adsorption mimics many of the same characteristics of solution-phase cage effects. That is, preadsorption dictates that translational motion of the photogenerated radicals is greatly influenced by the silica gel surface. The extent to which this motion is affected by the radical-pair multiplicity and by temperature varies with the chemical character of the surface, but is rather insensitive to the state of hydration of the silica gel and the presence or absence of co-adsorbates. That no rearrangement products were formed in homogeneous solution from the same substrates implies that restricted motion indeed influences the subsequent reactivity of surface-bound reagents. For example, the yield of photo-Fries rearrangement product derived from amides on silica gel is much higher than in solution [77], with a much larger proportion of the *para* isomer.

Stereochemistry is also affected in a significant way by surface adsorption. When enone photocycloadditions are allowed to occur as adsorbates on silica gel or alumina, larger fractions of reaction product derived from attack on the more hindered β face are observed. Thus, surface adsorption apparently influences conformational inversion, enhancing the formation of *trans*-fused products. This effect is synthetically useful, for sometimes a complete reversal of stereochemistry is observed compared with that seen in methanolic solution.

The surface also presents a highly polar environment that can favor formation of polar products. In the photooxidation of basic aqueous triethanolamine sensitized by $\text{Ru}(\text{bpy})_3$ and mediated by N,N' -bis-(3-sulfonatopropyl)-2,2'-bipyridine, SiO_2 colloids stabilize intermediates that bear electrostatic charge, in contrast with the suppression of hydrogen evolution in homogeneous aqueous solution under similar conditions [78]. The surface charge of the particles assists in charge transfer within the cage, repelling the reduced bipyridinium product and thus retarding the recombination rate. Other profound shifts in reaction rate are observed upon changing the ionic strength and pH of the contacting solution, and similar effects have also been observed on other metal oxide colloids [79, 80], and when the colloids are trapped within micelles, vesicles, and so forth. The pH also affects the rate of photocatalytic degradation, presumably because of adsorption effects [81, 82].

Physical techniques for evaluating surface polarity led deMayo and coworkers to assign relative rates of reaction on silica gel particles from shifts in the absorption spectra of absorbed spiropyrans [76, 77]. Similarly, Darwent and coworkers demonstrated that kinetic salt effects correlate with surface charge and with zeta potential measurements on colloidal titanium dioxide [80].

On metal oxide and metal chalcogenide semiconductor surfaces, multiple adsorption sites are accessible. On titanium dioxide, for example, there are acidic, basic, and surface defect sites available as likely targets for adsorption. Although the applicable adsorption isotherms differ at each site, selective activation toward a desired product on a specified semiconductor surface may indeed depend on photocatalyst preparation, which may in turn influence the relative fraction of each type of adsorption site. Although the number of basic sites can be determined by titration, the total number of acidic sites is more difficult to establish experimentally because of competitive water adsorption. Roughly, there are 2.4 times more acidic than basic binding sites on several of the commercially available TiO_2 .

In most photocatalysis, Langmuir–Hinshelwood kinetics is observed, suggesting the importance of substrate adsorption in key steps of the reaction [83]. That is, the rate of photocatalysis is proportional to the concentration (or pressure) of the reactant, which in turn can be related to the surface coverage Φ by the Langmuir expression, Eq. 8,

$$\Phi = KC/(1 + KC) \quad (8)$$

where K is the adsorption coefficient and C is the initial concentration of the reactant.

Occasionally, deviations from this simple expression have been observed, with most such observations being attributed to mechanistic complexity. For example,

the relative importance of the Langmuir–Hinshelwood mechanism relies entirely on the surface association of the adsorbed species, whereas the Eley–Rideal route takes place in such a way that the reaction proceeds by collision of a dissolved reactant with surface-bound intermediates [84]. In practice, however, both kinetic descriptions show the same kinetic profiles; this makes it difficult to unambiguously delineate the specific adsorption mode. Although similar kinetic profiles are shown for both transformations, trichloroethylene adsorbs at Ti sites by a π interaction, whereas dichloroacetaldehyde, an intermediate proposed in the photocatalyzed decomposition of trichloroethylene, is dissociatively chemisorbed by attachment of the α -hydrogen to a oxide surface site [85].

This surface-binding complexity is even further complicated by photoexcitation and by the presence of other adsorbates on the same surface. Detailed kinetic investigations have shown that adsorption and photoadsorption are influenced by thermal removal of water and surface hydroxyl groups [86]. Preadsorption of other reagents on SnO_2 can produce a substantial increase in oxygen photoadsorption under sub-band-gap irradiation and can shift the photosensitivity threshold to much longer wavelengths.

Thus, surface effects and adsorption equilibria can dramatically influence the relative reactivity of photoelectrochemical transformations. Not only does the surface effectively control the movement of reagents from the electrolyte to the photo-activated surface and the desorption of products (avoiding overreaction or complete mineralization), but it also influences the stability and accessibility of photo-generated intermediates toward secondary intermolecular reactions [87]. Because the efficiency of diffusion and mass transfer to and from the photocatalyst surface depends on the solvent and catalyst pretreatment, quantitative predictions of photocatalytic reactions have proved to be difficult, although the qualitative principles governing each step of these events can be easily recognized.

Surface properties of semiconductors can vary with size of the crystal or crystallite. In large crystals, electron delocalization is so extensive that the crystal properties are collective and bear no close resemblance to the electronic states of the components. The presence of highly crystalline phases at the surface of a semiconductor particle causes profound changes in structure, bonding, and reactivity of adsorbates, so that a moderate size cluster of the individual molecules must be formed before full solid-state properties will be observable. Reducing the size of the semiconductor particle from single crystal to colloids or clusters will eventually disrupt the macroscopic characteristics of the large particle and will significantly affect the course of photoinduced electron-transfer reactions [88–93].

The use of arrested precipitation to prepare sized semiconductor particles from solution has made it possible to prepare colloidal clusters of narrow size distribution. Dramatic blue shifts in the absorption maxima of such aggregates are observed as the colloidal cluster size is reduced; this is a consequence of the kinetic energy requirement for spatially localizing the electron-hole pair at neighboring sites in a small particle. ZnS crystallites with an average diameter of 20 Å, for example, exhibit an apparent band gap that is blue-shifted by about 0.6 V from that observed in bulk crystals. Even larger shifts are observed with HgSe and PbSe semiconductors, where, with diameter sizes less than 50 Å, the optical edge is shifted

by about 2.8 V. Although the chemical consequences of these electronic changes are still not clear, such quantum size effects are bound to influence photocatalytic activity. With such shifts, the flat-band potentials become slightly more negative and the surface charge shifts.

The rate of flow of electrons across the interface from such a charged particle depends on the availability of an accessible site for this transfer. Lattice defects provide sites where conduction-band electrons can be easily transferred through solid dislocation levels. Reduction sites for electron accumulation are usually provided by metalization of the semiconductor particle. This can be achieved through in situ reduction of metal salts, resulting in metal island deposition, or by a number of vapor-transfer techniques. The existence of such sites will thus control whether single or multiple electron-transfer events can actually take place under steady-state illumination.

The surface crystal structure and particle size can also influence photoelectrochemical activity. The mode of pretreatment, for example, dictates whether titanium dioxide exists in the anatase phase (as is likely in samples which have been calcined at temperatures below 500 °C) or in the rutile phase (from calcination temperatures above 600 °C) or as a mixture of the two phases for pretreatments at intermediate temperature ranges. The effect of crystalline phase could be easily demonstrated in the photocatalytic oxidation of 2-propanol and reduction of silver sulfate, where anatase is active for both systems. But when the catalyst was partially covered with platinum black, alcohol oxidation was easy, but silver ion reduction was suppressed. On rutile, redox activity was observed for Ag^+ , alcohol oxidation was negligible [85].

Particle-size control can also be afforded by the colloid being constrained to vesicles, membranes, or zeolites. With small particles or clusters, a range of oxidative efficiencies is observed by spectroscopic methods [94]. The observed rates are non-Arrhenius, which the authors explain to be a function of multiphonon electron tunnelling, probably to preexistent traps. The shorter lifetimes observed at shorter emission wavelengths were thought to indicate significant Coulombic interaction between traps. An intriguing recent report achieves size limitation of semiconductor electrodes by preparation by photolithography techniques. The use of specially designed particles with controlled size, morphology, surface catalysts, and dopants can surely influence the selectivity, which can ultimately be attained in photoelectrochemical conversions. Only very few explorations of these effects in organic systems have yet been made.

8.4.2 Potential Control

In principle, chemoselectivity should be achieved if the oxidation potential of a desired donor adsorbate lies between the valence-band edges of two possible semiconductor photocatalysts. Given that TiO_2 has a more positive valence-band edge than CdS , the former should be the more active photocatalyst. By switch of the excited photocatalyst from TiO_2 to CdS , the reactivity of the photogenerated hole toward oxidative activation is greatly changed. Consistent with this idea, decar-

boxylation of organic acids (Eq. 9) is much more efficient on irradiated suspensions of rutile than on CdS [95].

Chemical differentiation between two oxidizable sites in the same molecule can also be achieved in organic photocatalytic reactions by choice of a different semiconductor and thus adjustment of the electrochemical band-edge positions. Consistent with this idea, the photocatalytic oxidation of lactic acid on UV-irradiated platinumized-TiO₂ leads to decarboxylation, presumably through the singly oxidized carboxyl radical. In contrast, the same reagent on irradiated platinumized CdS leads to pyruvic acid by oxidation of the alcohol group (Eq. 10) [96].

Unfortunately, shifts in the valence-band edge position and in surface adsorptivity do not always give functional-group-specific oxidation or the expected order of reactivity. For example, different product distributions in oligopeptide formation were achieved by the light-responsive semiconductor being changed: diglycine is formed twice as efficiently on platinumized TiO₂ as on platinumized CdS, whereas pentaglycine is formed four times faster on CdS/Pt than on TiO₂/Pt [97]. Presumably, this imprecision reflects complicated dependence on electron-exchange reactions and kinetics governed by surface effects. For example, when potentiostatic oxidation of lactic acid was conducted in the dark on glassy carbon at +1.3, +1.5, or +1.6 V (potentials respectively less positive, nearly equivalent to, and more positive than the valence-band edge of CdS under photocatalytic reaction conditions), only decarboxylation could be observed. Furthermore, nearly equivalent current doubling was observed on both TiO₂ and CdS; this suggests no evident difference in the mechanism on these two materials, and that observed chemoselectivity may be more strongly influenced by adsorption differences on the semiconductor surface than by band-edge effects.

It is important to note that if the band edges of an illuminated semiconductor govern its photoelectrochemical reactivity, then experimental variation with solvent will take place, since the band positions of many common semiconductors [12, 20, 21] shift with changes in electrolyte. The shift of great importance in oxidative organic phototransformations is that of the conduction band edge. As the band edge moves above or below about -0.8 V, it loses or retains the ability to reduce adsorbed oxygen, for the reduction potential of oxygen in acetonitrile is -0.78 V. Thus, oxygen can assume a dual role in photocatalytic half reactions, either acting as an electron trap in generating superoxide on illuminated titania particles or as a chemical trap for singly oxidized organic intermediates produced on the photocatalytic surface.

Even though photoelectrochemical activation of rutile or anatase can thus be envisioned as a means for oxygen activation, and although most photocatalytic transformations are conducted in the presence of air, other acceptors with reduction potentials less negative than the conduction band edge can also act as electron traps. Flash photolysis of a colloidal suspension of TiO_2 in the presence of methyl viologen, for example, shows direct evidence (spectroscopic absorption) of the single-electron reduction product (Eq. 11) [98].

Thus, the band positions of the irradiated semiconductor are key thermodynamic variables for in the control of the observed redox chemistry resulting from photocatalyzed single-electron transfer (charge trapping) across the semiconductor–electrolyte interface. Whether oxygenation, rearrangement, isomerization, or other consequences follow this initial electron transfer seems to be controlled by surface effects on the relative rates of reaction.

8.4.3 Current Control

Ultraviolet irradiation of a photocatalyst creates an electron-hole pair, and hence activates the semiconductor surface, thereby offering several important advantages over analogous transformations that might take place in a standard electrochemical cell. An electron-hole pair on the surface of a metal oxide is sensitive to light flux, because control of the number of incident photons will also control interfacial current flow. Upon irradiation, semiconductor particles become active centers for electron exchange, but their activity is immediately extinguished as soon as interfacial charge transfer takes place. If the number of incident photons is low, the number of photogenerated electrons and holes available to each adsorbate will also be low. In turn, the observable quantum yield of products will be decreased [99–101]. The absorption spectrum of the semiconductor will also influence reactivity because of shifts in wavelength, and the characteristics of the semiconductor particle (crystal morphology, doping densities, or surface pretreatment) will influence the kinetics for subsequent reactions and hence the distribution of products induced by photoexcitation. The quantum efficiency can be therefore be enhance by intermittent irradiation alternating with an intervening dark period [100, 101].

In a conventional electrochemical cell poised at a high positive potential, oxidation of an adsorbed donor by interfacial electron transfer occurs readily. If the product of that single-electron oxidation is itself oxidized at the applied potential, a second electron also flows. This is a relatively common occurrence for substrates that undergo a geometry change after the initial oxidation, either by bond cleavage or by a twist about a multiple bond.

In contrast, photoelectrochemical activation depends on the trapping of the photogenerated electron-hole pair, usually by the capture of a highly oxidizing, surface-confined hole. But after interfacial electron transfer from an adsorbed donor has taken place, the hole is filled and further oxidation is blocked. Thus, because the number of adsorbed molecules is much higher at any time than the number of photogenerated holes on an irradiated surface, most photocatalytic transformations proceed through single-electron oxidation, even in reactants that participate in multiple -electron oxidation in conventional electrochemical cells.

This current-control feature can be illustrated in the electrochemical decarboxylation of vicinal diacids. These reagents have long been used as protecting groups for double bonds, since electrochemical deprotection by two-electron oxidation causes bis-decarboxylation and production of a C=C double bond [60]. In contrast, when platinized titanium dioxide is irradiated in the presence of one such vicinal diacid (cyclohexenedicarboxylic acid), the major reaction pathway leads to mono-decarboxylation, rather than to benzene formation (Eq. 12).

It is likely that this reaction takes place through a surface-adsorbed radical whose further oxidation is blocked by the immediate step in surface oxidation potential that accompanies interfacial electron transfer to trap the photogenerated hole. On the surface of a photocatalyst, this radical is reduced to an anion, and protonated, producing a C-H bond.

This control, of course, depends on the surface density of photogenerated holes, which in turn depends on incident light flux. At high incident light intensities, surface charge can accumulate, sometimes to a loading that permits electrophoretic mobility even of a quite large particle [102, 103]. When appropriately prepared, colloidal TiO_2 can apparently accumulate charge to directly effect multiple quanta redox reactions. Such charge accumulation produces charge densities that are directly related to the doping level of the semiconductor. Thus, pretreatment to influence the doping level not only alters band positions but may also improve the efficiency of photoinduced electron transfer, making even very difficult reactions possible. For example, the dispersal of Fe_3O_2 into doped TiO_2 produced a material with greatly improved properties for nitrogen reduction.

8.5 Selective Photoelectrochemical Transformations

The relevant principles influencing chemical selectivity in photoelectrochemical reactions having been discussed, we can now survey the use of such techniques in

organic chemistry. Although the quantum efficiency for some photoelectrochemical transformations can be quite low, the additional modes of chemical control afforded by adsorption and surface effects, by band-edge-dependent selectivity, and by Coulombic control of interfacial electron transfer make the use of photoelectrochemical activation an attractive synthetic technique.

8.5.1 Oxidations

Most common metal oxide and metal chalcogenide semiconductors have valence-band edges that lie positive of the oxidation potentials of most organic functional groups, and thermodynamics will thus favor photocatalytic oxidation. For efficient processes to take place, an easily oxidizable donor is required, but a whole range of substrates have been shown to be useful for this application. For example, a Japanese group has shown that this purpose is served not only by pure compounds, but even by wastes such as polyvinyl chloride, algae, protein, dead insects, and animal excrement, which function as electron sources [104]. Thus, synthetic utility is attained only if this wide reactivity is controlled. In practice, selectivity is best controlled by the adsorption and oxidation potential effects [105].

Given that single-electron oxidation is mechanistically important in these reactions, the thermodynamic criteria discussed earlier can be used, together with the known reactions of cation radicals, to predict new organic oxidation products. For example, there is a wide variety of oxidations that proceed by photoelectrochemical methods. Alcohols, for example, can be oxidized to the corresponding carbonyl compounds in high yield [106–118] (Eq. 13).

In fact, primary alcohols can be selectively oxidized to the corresponding aldehydes, without appreciable overoxidation, whereas poorer yields were obtained with secondary aliphatic aromatic alcohols [106c]. Similarly, phenols can be converted to quinones [118]. The efficiency of the photocatalytic oxidation depends on the pretreatment and size of the photocatalyst [119], and analogous conversions are also obtained on heteropolyacids, which can be considered soluble analogs of TiO_2 suspensions [120].

Anatase is much more active than rutile in the liquid-phase photooxidation of 2-propanol, and the observed reactivity compared well with that of gaseous alcohol on platinized titania [106a]. Because most early studies employed the alcohol as a sacrificial reagent for the photochemical production of hydrogen, the organic product was often not analyzed and little effort was devoted to the selective activation of alcohols in the presence of other functional groups. In the oxidation of car-

bohydrates, for example, complete oxidative conversion to hydrogen and carbon dioxide was a primary goal [109]. Even with this orientation, however, it is clear that the chemical structure of the alcohol affected the quantum yield of hydrogen, with methanol and ethanol being more efficiently oxidized than other primary alcohols, and water being oxidized as least four times less efficiently than methanol [110].

The effect of doping could be easily explored in this series. For liquid-phase alcohol photooxidations, best photoefficiency was attained with a platinum loading of TiO_2 of 0.1–1 weight %, and other noble and transition metals, when deposited on the metal oxide photocatalyst, also enhanced the photoredox reactivity, in the decreasing order $\text{Pt} > \text{Rh} > \text{Pd} > \text{Ru} > \text{In}$ [111]. Pretreatment of the photocatalysts at high temperature often enhanced hydrogen evolution, as did the presence of transition metal oxide dopants. Vanadium and molybdenum oxides present on the surface of TiO_2 , for example, increased the rate, but decreased the selectivity, in the thermal oxidation of methanol, but decreased its photocatalytic activity [112]. The addition of alkali metal salts similarly shifted the selectivity in the photooxidation of aqueous methanol toward water, and induced further oxidation of acetaldehyde and acetic acid, the partially oxidized products derived from methanol [113]. With metallic nickel as a support, 2-propanol could not be photocatalytically oxidized on SrTiO_3 , CdS , or TiO_2 without water, and no hydrogen evolved if oxygen was present [113]. A mechanism focusing on surface binding to a hydroxyl group at acidic sites was implicated.

In only a few of these studies was chemical selectivity considered. For example, primary alcohols could be selectively oxidized to the corresponding aldehydes, without appreciable overoxidation, when the platinized TiO_2 photocatalyst was suspended in benzene (Eq. 7). Poorer yields were obtained with secondary aliphatic or aromatic alcohols [106c]. In photodehydrogenation of mixtures of ethanol and D_2O , D_2 was found to be the major gaseous product, suggesting selective binding of water. In the photooxidation of sorbitol, the photocurrents produced on illuminated TiO_2 were found to depend on molecular structure (chain length and the number of OH groups). The reactions were pH dependent and the effects were ascribed to the high concentrations of OH groups at the photoactivated surface when long-chain polyols were adsorbed [116]. The photoelectrochemical oxidation of primary or secondary tertiary alcohols was much more difficult than that of primary or secondary alcohols, and primary sites could be oxidized selectively in the presence of secondary ones.

Quantum efficiencies for photooxidation were improved by platinization of the TiO_2 photocatalyst, with the observed yield increasing linearly with platinum coverage [117–121]. Acetone was the major product in the presence of air or silver ion, a result that was similar to those observed upon γ irradiation or in the Fenton reaction. This similarity was interpreted as implying hydroxyl radical mediation of the observed oxidations.

In the photooxidation of phenol on an irradiated suspension of titanium dioxide, the hydroxyl radical was also directly implicated as the reactive species [122], with oxygen incorporated in the observed organic products (Eq. 14) [118].

On further photolysis, aldehydes, acids, and CO_2 could be obtained. Selectivity was attained within a series of chlorinated phenols [122], and the rate of phenol oxidation depended on the coadsorption of Fe^{3+} or Ag^+ onto the surface of the photocatalyst [123].

Organic compounds bearing heteroatoms from the same column in the periodic table also react by similar paths. Photocatalytic oxidation of primary amines on irradiated semiconductor suspensions, for example, forms Schiff bases which can couple with the starting amine [124]. Two different products are formed, depending on the initial concentration of the amine and on the nature of the semiconductor catalyst (Eq. 15) [125].

Formylation was also observed when the amine conversion was carried to high conversion. Secondary amines are obtained from primary amines, and diamines can be cyclized photoelectrochemically.

If the photocatalytic irradiation is conducted in the presence of an alcohol, *N*-alkylation is observed (Eq. 16) [126].

The photoefficiency varied with alcohol structure: ethanol > methanol > 2-propanol > *tert*-butanol. If the reaction is conducted under a hydrogen atmosphere, the production of amines is enhanced, a process which was inhibited by oxygen. Amines bearing α -hydrogens react by carbon-carbon coupling at the α -positions, as do ethers and some substituted alcohols [115a]. On colloidal ZnS, for example, α -coupling, presumably through a radical produced by deprotonation of the photo-generated radical cation, is observed with amines (Eq. 17) as well as with ethers and alcohols.

Cleavage adjacent to nitrogen was also observed in the photoelectrochemical demethylation of methyl orange [127]. Photocatalytic cleavage of an *N*-methyl group was competitive with C–N cleavage adjacent to the azo linkage.

The photoelectrochemical activation of aryl amines also produces coupling at nitrogen. With toluidines, for example, azo products are formed (Eq. 18) [128].

Formation of a nitrogen radical by N–H deprotonation must be faster than α -deprotonation of the pendant alkyl group. Similarly, pyrrole could be photopolymerized [129] and picolines could be photocatalytically degraded [130].

Amides are oxidized to either imides or α,β -unsaturated amides [131, 132], sometimes quite chemoselectively (Eq. 19). Lactams can be photocatalytically converted to imides (Eq. 20), but if the reaction is conducted in the presence of Cu(I), unsaturation is induced instead.

The oxidative photoelectrochemical synthesis of amino acids from simple molecules (ammonia, methane, and water) has been reported [133, 134]. Low efficiencies were observed in the conversion of mixtures of methane, ammonia, and water to several amino acids on platinized TiO_2 . Amino acids and peptides were formed when glucose replaced methane as the carbon source in a parallel experiment. Higher quantum efficiencies (20–40 %) were observed in the conversion of α -keto acids or α -hydroxy acids to the corresponding α -amino acids, and moderate levels of enantiomeric selectivity (optical yields of about 50 %) were reported when chiral starting materials were employed.

The resulting amino acids are coupled to oligopeptides on irradiated TiO_2 [97].

The molecular weight distribution of the peptides could be partially controlled by choice of the sensitizer: diglycine was formed twice as efficiently on platinized titanium dioxide as on platinized cadmium sulfide, whereas the yield of pentaglycine was four times higher on CdS/Pt than on TiO₂/Pt.

Thioethers convert cleanly to the corresponding sulfoxides [135], (Eq. 21), even in competition with other oxidizable groups [136, 137].

Not surprisingly, thiols can be oxidized cleanly to disulfides [138], as in the CdS-photocatalyzed conversion of cysteine to cystine, where the uptake of oxygen was pH dependent. The reaction rate was not increased in deuterium oxide nor decreased by added azide, suggesting that singlet oxygen is not involved. Superoxide dismutase did inhibit the conversion. Phosphines and phosphonic acids undergo similar oxidative transformations [139].

Photocatalyzed oxidative decarboxylation of carboxylic acid is an important oxidative degradation route [140–144]. Simple carboxylic acids suffer photo-Kolbe decarboxylation under the usual photoelectrochemical conditions (Eq. 9). In the decarboxylation of acetic acid on an irradiated *n*-TiO₂ single crystal or polycrystalline electrode, for example, ethane was formed, whereas methane was produced on irradiated TiO₂ powders. Depending on the identity of the semiconductor, the extent and identity of the adsorbed metal, and the pH of the solution, the extent of alkyl coupling as opposed to reduction could be closely controlled. The different reactivity observed on dark electrodes and illuminated powders probably derives from the different space-charge thickness developed on each surface. On a powder, a newly formed radical will persist until it is trapped by a co-adsorbate or until back electron transfer generates an anion, protonation of which allows for surface desorption. The critical involvement of alkyl radicals has been established in spin-trapping experiments, although deuterium incorporation seems to implicate the eventual protonation of an anionic intermediate.

Consistent with this idea, the photocatalyzed decarboxylation of oxalic acid was found to be controlled by surface properties and by the presence of recombination centers, which in turn depended on the photocatalyst preparation method [142]. Analogous results have been observed in the photodecarboxylation of pyruvic acid [143] and formic acid [144].

As we saw earlier [60, 145] with vicinal diacids, mono- or bis-decarboxylation occur, depending on incident light flux (Eq. 12). At low light flux, the primary product is that of monodecarboxylation. Multiple carboxylic acids such as ethylene diaminetetracarboxylic acid also suffer decarboxylation under photocatalytic oxidation conditions [146].

Carboxylic acids have also been converted to the corresponding fluoride upon irradiation of TiO₂ suspended in an aqueous solution also containing silver fluoride [147] (Eq. 22).

In the conversion of di- and triphenylacetic acid to the corresponding fluorides, laser flash photolytic investigations demonstrated that a carbocationic intermediate was trapped by fluoride in the key step. This interesting conversion was claimed to take place through a two-photon process in which the photocatalytically generated radical remains bound to the surface of the photocatalyst, then trapping a second photogenerated hole to produce a carbocation.

The surface-enhanced carbon-carbon coupling of radicals required for carbon-carbon bond formation in the photo-Kolbe reaction could also be observed with other surface-generated radicals. Cyclic allylic ethers are deprotonated at the position adjacent to oxygen under photoelectrochemical activation, producing radicals that can dimerize or be trapped with oxygen [148] (Eq. 23).

As the photocatalytic carbon-carbon bond is formed, hydrogen evolves when the photocatalytic activation is done on colloidal ZnS [149, 150]. This dehydrodimerization also takes place with saturated ethers, with reactivity related to C-H bond strength. Thus, 2,5-dihydrofuran (an allylic ether) is more easily activated than the isomeric 2,3-dihydrofuran (a vinyl ether). With the former substrate, all three diastereomeric coupling products are observed. Water is required for the reaction, and the primary photochemical product is thought to be a surface-bound hydroxyl radical.

Photocatalytic activation of allyl and benzyl ethers results either in carbon-carbon coupling or oxygenation [148-151]. The photocatalyst used for these conversions can be generated in situ, by photolysis of a zinc dithiolene salt, by pre-formed catalysts, or by particles supported within surfactant vesicles. Radical intermediates formed by hydrogen abstraction by photogenerated hydroxyl or hydroperoxyl radicals may also be important in the photoelectrochemically induced oxidation of hydrocarbons. In the TiO₂-sensitized photooxidation of toluene to cresols, for example, a photo-Fenton (radical) type mechanism has been suggested [150].

Radical cations are probably involved in the photooxidation of olefins [1-7, 24, 50-54, 56, 61, 66] (Eqs. 2 and 5). Many oxidizable arenes and dienes are, similarly, oxidatively cleaved or rearranged by routes consistent with initial formation of a radical cation. As we saw above, the observed oxidative cleavage product probably derives from the combination of a surface-bound radical cation with superoxide or adsorbed oxygen. With alkanes or simply substituted alkenes, however, the capture of a photogenerated hole is often thermodynamically forbidden. Thus, instead of radical cations, radicals formed by hydrogen atom abstraction by an activated oxygen species dominate the observed chemistry. With alkanes, oxygenation at sites

controlled by radical stability, rather than oxidative cleavage, is observed [151–153]. The relative ratio of oxygenation to complete mineralization can be controlled, at least to some extent, by careful choice of the metal oxide photocatalyst

In fact, the surface significantly affects the distribution of products observed from the initially formed radical cation [154]. Surface control of the competition between deprotonation and oxidative cleavage of a photoelectrochemically generated radical cation can be seen in the divergent chemistry attained from the 1-methylnaphthalene cation radical formed on irradiated TiO_2 powders and by homogeneously dispersed single-electron oxidants (Eq. 6) [60]. Here the semiconductor surface delivers the co-adsorbed oxygen or superoxide to the π system more rapidly than C–H deprotonation can take place.

Aromatic hydrocarbons can be oxidatively cleaved either on a side chain or in the ring (Eq. 6) [60]. Even saturated hydrocarbons can be induced to become oxygenated or to participate in isotope exchange on irradiated platinum/ titanium dioxide catalysts [151, 155, 156]. Competitive trapping of the photogenerated conduction band electron by adsorbed protons is thought to be responsible for the reduced contribution of oxygen at lower pH.

The observation of products at intermediate oxidation level in the photocatalytic reactions of hydrocarbons is consistent with a surface-bound radical intermediate [157]. Photocatalytic isotope exchange between cyclopentane and deuterium on bi-functional platinum/titanium dioxide catalysts indicates the importance of weakly adsorbed pentane at oxide sites. The platinum serves to attract free electrons, decreasing the efficiency of electron–hole recombination, and to regenerate the surface oxide after exchange. Much better control of the exchange is afforded with photoelectrochemical than thermal catalysis.

Water oxidation cannot be solely responsible for the observed chemistry, since toluene as a neat liquid can be oxidized to benzyl alcohol (Eq. 24) [151].

Here the intervention of the hydrocarbon radical cation seems possible. Hydrocarbon photocatalyzed oxidations seem to depend significantly on the relative positions of the valence-band edge of the active photocatalyst and the oxidation potential of the substrate. For example, in contrast to the photocatalytic oxidation of toluene described above, lower activity was observed in neat benzene, despite the fact that its oxidation potential lies at or slightly below the valence-band edge. This observation implies the importance of radical cation formation (by photoinduced electron transfer across the irradiated interface) as a preliminary step to hydrocarbon radical formation. If the benzene is dispersed into a benzene-saturated aqueous solution into which the semiconductor is suspended, complete mineralization is attained [158]. Thus, to observe selective photoelectrochemistry, it is necessary to avoid primary formation of the highly reactive, nonselective hydroxyl radical (formed by water oxidation) by the use of an unreactive, but polar, organic solvent.

Complete mineralization of alkyl [159, 160], vinyl [161], and aryl [162–164] halides, as shown in Eq. 25, for example, probably requires the generation of a photogenerated hydroxyl radical. These reactions figure prominently in current photocatalysis applications dealing with environmental purification.

The most important class of photocatalytic transformations is the oxidation of a range of organic substrates. This reactivity follows from either trapping of an electron–hole pair to produce a photogenerated surface-adsorbed radical cation or from radicals produced by activated oxygen radicals (surface oxides or adsorbed hydroxyl, hydroperoxyl, or peroxy radicals) [165]. Thus, photoelectrochemistry is an excellent means for initiating chemoselective oxidation.

8.5.2 Reductions

Many fewer photocatalytic organic reductions have been reported. Reductions of organic substrates are less thoroughly studied, largely because of the early emphasis on the use of organic compounds as oxidizable source for the production of hydrogen gas. Nonetheless, some examples do exist, such as the hydrogenation of olefins, vinyl ethers, and α,β -unsaturated enones and alkynes [166, 167]. Similarly, other multiple bonds can be reduced, e.g., the N=N double bond of diaryl azo compounds [168] or carbonyl C=O bonds [169, 170].

When oxygen is specifically removed from a photocatalysis mixture, other reagents can accept the photogenerated conduction-band electron. Because of the only modestly negative potential of electrons at the conduction-band edge of conveniently accessible semiconductors, few organic substrates can fill this role. Cationic organic reagents are, indeed, reduced in this potential regime, as in the photoinduced reduction of methyl viologen and comparable derivatives (Eq. 11) [171].

Catalytic hydrogenations can be induced by the reduction of protons present in aqueous acid, especially on metalized semiconductor suspensions. For example, the oxidative chemistry reported earlier for cyclohexene-4,5-bis-dicarboxylic acid (Eq. 12) is suppressed if the reaction is conducted in the absence of oxygen in aqueous nitric acid. Under those conditions, catalytic hydrogenation of the double bond becomes a major pathway (Eq. 26) [60].

Analogous photoelectrochemical hydrogenations of double and triple bonds have also been reported with other oxidizable sacrificial donors (Eq. 27) [166].

With CdS metalized with platinum or rhodium as the photocatalyst, hydrogenation was about four times more efficient than hydrogen evolution, with the observed efficiency depending on the solution-phase pH and the identity and loading of the metal catalyst.

By these same routes, olefins, vinyl ethers, and α, β -unsaturated enones could be photoelectrochemically hydrogenated on TiO_2 in the presence of ethanol as sacrificial oxidant [166–168]. With 2-methyl-2-pentene, hydrogenation occurred in 63% yield, without side products (Eq. 28).

The photoelectrochemical reduction of the $\text{N}=\text{N}$ double bond of methyl orange, a diaryl azo dye, can be similarly sensitized by colloidal titanium dioxide [168]. The reaction was sensitive to pH and the identity of the organic redox reaction could be shifted by conducting the photoreaction in the presence of cationic surfactants, which increased the efficiency of oxidative cleavage by inhibiting charge recombination [127]. Reduction was favored when polyvinyl alcohol was used instead. The ambident photoactivity of methyl orange thus makes it an attractive probe for the activity of irradiated semiconductor suspensions.

Photoelectrochemical reduction of double bonds also takes place on ZnS sols. For example, efficient photodisproportionation of aldehydes, that is, a photo-Canizzaro reaction, can be observed on suspensions prepared from cold oxygen-free aqueous solutions of ZnS and Na_2S (Eq. 29) [169].

In the same way, acetaldehyde produces ethanol and acetic acid, together with smaller quantities of biacetyl and acetoin. The relative paucity of photoelectrochemically induced reductions makes this an interesting area for further investigation.

Selective reduction of a halogenated aromatic nitro compound to the corresponding hydroxylamine or amine upon irradiation of TiO_2 suspended in degassed alcohol has also been reported, as has the selective photoreduction of *p*-nitrobenzaldehyde to the corresponding aldehydic aniline (Eq. 30) [170], and alkyl azides can also be reduced to the corresponding amine.

The synthesis of a benzimidazole through reductive photocatalysis has also been described [172]. Although the reduction of N_2 to ammonia was claimed to be induced by photocatalysis on TiO_2 [173], the reproducibility of this reported result was challenged [174].

The photocatalytic reduction of various metal salts has been a primary route for the preparation of metallized semiconductors, as well as in the detoxification of metal-contaminated waste streams [175], but the details of such reactions are beyond the scope of this article.

8.5.3 Cycloadditions and Retrocycloadditions

The ubiquitous and reversible formation of radical cations in photoelectrochemical transformations allows pericyclic reactions to take place upon photocatalytic activation since the barriers for pericyclic reactions are often lower in the singly oxidized product than in the neutral precursor. For example, ring openings on irradiated CdS suspensions are known in strained saturated hydrocarbons [176], and formal $[2 + 2]$ cycloadditions have been described for phenyl vinyl ether [177] and *N*-vinyl carbazole [178]. The cyclization of nonconjugated dienes, such as norbornadiene, have also been reported [179]. A recent example involves a 1,3-sigmatropic shift [180].

Several reactions that can formally be classified as cycloadditions or retrocycloadditions take place in homogeneous solution with single-electron oxidative initiation, so the observation of parallel activity on irradiated semiconductor suspensions is certainly reasonable. Photocatalysis by ZnO or CdS induces the ring-opening of several highly strained hydrocarbons, in parallel to the analogous reactions taking place in the dark upon exposure to a single-electron oxidant, ceric ammonium nitrate [76]. The observation of quantum yields greater than unity in the valence isomerization of hexamethyl(dewarbenzene) to hexamethylbenzene, Eq. 31, suggests that a surface-bound cation radical-chain mechanism may be involved.

Different pretreatment of CdS gave rates that varied only by a factor of about two. Thus, surprisingly, different surface areas, impurities, and surface structures seem to play only a minor role in this reaction. Anthracene [177] and quinolone [176] dimers could also be opened in similar fashion.

Ring formation takes place in the photodimerization of unsaturated ethers and amines, such as phenyl vinyl ether and vinyl carbazole (Eq. 32).

The presence of both stereoisomers in this dimerization implies that a stepwise process involving cation radicals is probably involved. A detailed kinetic and product study showed that when the reaction was conducted on ZnO, variations in the surface composition had a major effect on both the rate and stereochemistry. Thus, the effect of various quenchers could be explained as competitive adsorption at active sites, with or without interference with electron transfer. Neither particle size, surface area, nor crystal structure appeared to significantly influence the CdS photocatalyzed dimerization of *N*-vinylcarbazole [179].

Intramolecular cycloadditions can also be induced by photoelectrochemical activation. Norbornadiene, for example, can be cyclized upon irradiation of ZnO, ZnS, CdS, or Ge semiconductors [179].

8.5.4 Geometric Isomerizations

When exposed to CdS excited with light of an energy greater than its band gap (Eq. 3), the *cis* and *trans* isomers of substituted stilbenes achieve thermodynamic equilibrium [181]. Given that the reaction was quenched by electron donors (methoxybenzenes or pyrenes) and is affected by the ratio of substrate to catalyst, light intensity, and temperature, a radical cation is the likely intermediate, as was discussed earlier for the related styrenes. Oxygen suppressed the reaction [182], producing instead oxidative cleavage products [53]. When a Hammett plot was constructed for the rate of isomerization of *p*-substituted stilbenes, a sharp break at $\sigma = 0.19$ occurred; this indicates a change in the rate-determining step with a change of the electron-donating ability of the substituent. The two regions would represent endothermic and exothermic hole trapping, respectively, with a ρ value (-0.74) reminiscent of that previously observed for the oxidative cleavage of diphenylethylenes [53]. Surface precomplexation would be expected to diminish the observed ρ value.

A Stern–Volmer plot for photocatalytic stilbene isomerization also has both curved and linear components [183]. This requires at least two separate mechanisms

that differ as to whether the adsorption of the quencher on the surface competes with that of the reactant or whether each species has a preferred site and is adsorbed independently. In both mechanisms, quenching of a surface-adsorbed radical cation by a quencher in solution is required. Similarly, the geometric isomerization of simple alkenes on irradiated ZnS suspensions exhibited high turnover numbers; this indicates that trapped holes derived from surface states (sulfur radicals from zinc vacancies or interstitial sulfur) play a decisive role.

Thus, as with the oxidative cleavages, transient formation of a surface-adsorbed radical cation is likely in photoelectrochemically induced geometrical isomerizations.

8.5.5 Miscellaneous Reactions

Several other notable organic transformations can be observed on irradiated semiconductor particles, but the paucity of work on organic photoelectrochemical conversions, apart from redox chemistry, shows that many possibilities remain for finding synthetically useful variants of photocatalysis. Visible-light irradiation of metal chalcogenides, for example, CdS, can induce what appears to be a symmetry-forbidden [1, 3] sigmatropic shift of hydrogen (Eq. 33) in the absence of oxygen [180].

The reaction was at least partially intramolecular, so that it is necessary to consider a radical cation-mediated hydrogen shift which would have been forbidden in the ground-state neutral precursor. In a second example, photoinduced Michael-like reactions have also been observed when α,β -unsaturated acids were used as substrates for amino acid synthesis [184].

8.6 Conclusions

Although photoelectrochemistry has been known as a field for over thirty years, its full impact on organic synthesis has yet to be revealed. This article has dealt with a variety of examples that show how chemical conversions can be induced by photoelectrochemical activation of light-sensitive semiconductor surfaces. Photoexcitation causes the promotion of an electron from the valence band to the conduction band, thus producing a surface-confined electron-hole pair. The charges represented by this pair are then trapped by interfacial electron transfer. The oxidized and reduced

species thus produced undergo dark secondary reactions which are greatly influenced by the surface on which they are produced.

Water is one possible hole trap, conceivably the dominant one in aqueous solution. The hydroxyl radical thus produced is a key intermediate in many oxidative degradations observed on irradiated metal oxide suspensions [185]. For many organic transformations, the key intermediate is the singly oxidized radical cation derived from the molecule of interest that was selectively adsorbed on the photocatalyst surface. The presence or absence of oxygen is also vitally important in defining subsequent reaction pathways.

Net chemical transformations observed in photocatalysis are thus controlled by band-edge positions, by adsorption effects, and by light-influenced current density. The surface can act to assemble co-adsorbates and can significantly influence the local polarity of photogenerated intermediates produced on that surface. Oxidations, reductions, cycloadditions, retrocycloadditions, and geometric isomerizations have been observed on these photocatalytic surfaces, often in high chemical yield. As with all such transformations, the utility of such new chemical processes lies in the chemist's ability to specify stereochemistry and regiochemistry or to activate a specific functional group in a complex molecule, or to choose a particular substrate from a mixture. It is here that a substantial challenge remains, as little is currently known about the detailed effect of the surface on secondary reactions of surface-bound intermediates. Nonetheless, photoelectrochemistry provides a useful new technique for the control of organic redox chemistry.

Applications of photoelectrochemistry in problems related to environmental issues are manifold, and have been the central focus of much work in this field conducted over the last decade. Although practical applications are still evolving, many of the transformations discussed here will represent key steps in the oxidative degradation of many contaminants. For example, the conversion of acetic acid to methane, the oxidative decomposition of biomass, and the photodegradation of organochlorine compounds, in this article discussed from the view of their synthetic utility, along with the photochemical recovery of toxic or precious metals also represent important social uses of solar energy. These reactions may also be involved in the dissolution of minerals, in the generation of biologically active oxidants or metabolites, or in the reduction of chemisorbed nitrogen on titanium-rich desert sands. The photoelectrochemical reduction of CO_2 also opens the possibility that organic feedstocks might one day be derived from aldehydes and alcohols produced by photoelectrochemical reductions [186].

Acknowledgments

Our program in organic photoelectrochemistry and chemically modified electrodes has been supported for many years by the U.S. Department of Energy, Office of Basic Energy Sciences; our investigation of surface-adsorbed radical ions has been supported by the National Science Foundation. I am also grateful to Professor James K. Whitesell for helpful discussions and assistance in illustrating this manuscript.

9 Radiative Charge Recombination and Electrochemiluminescence

Ann-Margret Andersson and Russell H. Schmehl

9.1 Introduction

The topic of radiative charge recombination encompasses a variety of areas including decomposition of reactive organic substances by redox pathways, simple annihilation of the one electron oxidized and one electron reduced forms of a particular substance and complex charge annihilation processes in microheterogeneous environments. Luminescent charge recombination processes are attractive for analytical applications because an optical signal can be generated from chemical systems subjected to electrolysis. As a result, a rich array of applications has sprung forth from studies of electrogenerated chemiluminescence and electroluminescence.

The first observation of luminescence associated with a charge recombination process came in the early part of the 20th century in experiments involving oxidative electrolysis of aqueous halide solution at mercury anodes [1]. The report describes the observation of colored “flames” from the mercury pool surface following formation of a coating of mercury halide on the electrode surface during electrolysis and the authors relate this to flame emission of mercury halides.

Many years passed before systematic studies of luminescent charge recombination came in the 1960s from several groups [2, 3, 4, 5]. In part, the study of radiative charge recombination was limited by the difficulty posed in generating and manipulating the reactive species. Advances in techniques for handling air-sensitive materials and the development of modern electroanalytical methods made the study of emissive charge annihilation processes more straightforward. The phenomenon is of both practical and theoretical interest and the literature today on this topic is broad in scope.

This chapter will focus on processes leading to the formation of localized excited states, excimers and exciplexes by annihilation of radical ions in solution. The article will not deal with either direct absorption or emission from intramolecular charge-transfer excited states. In addition, the voluminous literature in this area prohibits any attempt to comprehensively cover published work in the space avail-

able. The chapter will also focus on electrogenerated chemiluminescence (ECL) and electroluminescence (EL). A number of reviews present overviews of ECL [6, 7, 8, 9] and EL [10]. Additional articles exist that emphasize techniques for generation of ECL [11] and analytical applications [12]. A brief discussion of experimental aspects and applications will be presented here, but the emphasis will be on mechanistic aspects of radiative charge recombination and applications.

9.2 Processes Leading to Radiative Charge Recombination

9.2.1 Annihilation of Anion and Cation Radicals

To create an excited state in a charge recombination (or annihilation) process, the free energy of the process must be large enough to generate an excited state of one of the reaction products. For systems involving organic radical ion reactants (both doublet states), annihilation can result in either singlet or triplet excited states, as shown in Eq. 1.

The free energy of the annihilation reaction can be evaluated from the one-electron potentials for oxidation and reduction of the species involved and the zero-zero emission energy, E_{00} , of the luminescent product. The excited state formed can be either singlet or triplet spin multiplicity (or both). If strict spin conservation is observed in the process, the products will contain 75 % triplet and 25 % singlet; however, hyperfine interactions provide alternate avenues for angular momentum conservation [13, 14].

It is possible that some cases for which annihilation appears favored by Eq. 2 will not result in formation of an excited state. The simple expression does not account for differences in solvation energies and entropic factors for the redox processes which are generally in the range of 0.1–0.2 eV.

Figure 1. Energy level diagram for charge annihilation processes. Relative energies are shown for the DPA^+ , DPA^- pair, the TMPD^+ , DPA^- pair and the singlet and triplet excited states of DPA. The allowed recombination processes are indicated by the arrows.

A typical energy level diagram, with 9,10-diphenylanthracene (DPA) as an example, is shown in Figure 1. Annihilation of DPA cation and anion radicals results in the formation of the singlet excited state of diphenylanthracene, and fluorescence is observed. In general, for cases where A^+ and D^- differ, only one of the two product species has an accessible excited state. Figure 1 also depicts such a case for reaction of DPA^- with the N,N, N',N'-tetramethylphenylene diamine cation radical (TMPD^+). The energy available in the annihilation reaction is far below that required to produce either singlet state and only the DPA triplet is formed initially. However, fluorescence is also observed upon annihilation of DPA^- and TMPD^+ ; the fluorescence results from triplet-triplet annihilation (Eq. 3). Since fluorescence is observed in systems exoergic enough to populate the singlet excited state of the

chromophore directly and in systems clearly lacking sufficient energy, the former are referred to as energy-sufficient annihilation processes and the latter are energy-deficient.

9.2.2 Excimer and Exciplex Emission

Charge-annihilation processes preceding emission may occur from solvent-separated or contact ion pairs, and there is a possibility that excited-state dimers

Figure 2. Emission from a solution containing pyrene (0.005 M) (top) and pyrene (0.005 M) plus TMPD (0.001 M) (lower three spectra), which show fluorescence prior to electrolysis, electrogenerated chemiluminescence and post-electrolysis fluorescence (top to bottom), (with permission of the American Chemical Society).

(excimers) or excited-state intermolecular charge-transfer complexes (exciplexes) may form [15]. Excimers and exciplexes have shallow energy minima at energies lower than the localized excited state of the luminescent chromophore, and emission can occur from this weakly bound state to the ground state. Excimer emission has been observed from pyrene dimers following reaction of TMPD^+ and pyrene anion (PY^-). It has been observed that, for the $\text{TMPD}^+/\text{PY}^-$ system, both ^1PY localized fluorescence and $^1(\text{PY})_2$ excimer emission occur, but the excimer emission is much more intense than that observed upon direct excitation of pyrene [16]. Figure 2 illustrates the emission observed following direct excitation of pyrene and following annihilation of the radical ions. The explanation for the larger fraction of excimer emission from the redox reaction can be found in the fact that triplet-triplet annihilation is required for an emitting excited state to be produced following the charge-recombination process, and this reaction requires an intimate encounter of two pyrene molecules.

Other reactions of aromatic hydrocarbon anion radicals and amine cation radicals lead to exciplex emission, particularly in nonpolar solvents [15]. Luminescence from exciplexes is most definitively observed in systems for which the redox reaction is energetically unable to yield a localized excited state. The free energy of exciplex formation, ${}^{1,3}E_{\text{exc}}$, is associated with solvation and geometry optimization in the encounter complex of D^- and A^+ .

This is exemplified by the reaction of benzophenone anion with the tri(tolylamine) cation (TPTA⁺) in THF [17]. Formation of all triplet and singlet locally excited states for this system is not thermodynamically possible, yet broad, unstructured red emission is observed and was assigned to the exciplex.

Weller and Zachariasse thoroughly investigated exciplex formation and luminescence for donor acceptor systems in THF [18]. A particularly interesting result from their work came from an examination of the temperature dependence of radiative charge recombination between 9,10-dimethylantracene anion (DMA⁻) and TPTA⁺ in THF [19]. They found that both exciplex emission and fluorescence from DMA* were observed in solution at low temperature (ca. -50°C). As the solution temperature is raised, the excimer emission decreases in relative intensity, and at room temperature the emission is nearly completely DMA* fluorescence. The monomer-to-excimer emission intensity ratio as a function of temperature follows Arrhenius kinetic behavior and yields an activation barrier that is nearly the same as the energy gap between the exciplex and the ¹DMA* states. Thus, their model consisted of reaction of the solvent-separated ions to form an intimate emissive ion pair which could dissociate to yield the singlet anthracene derivative.

9.2.3 Reactions of Radical Ions with Other Reagents

Another approach for generating excited states by charge-recombination reactions involves the generation of a single radical ion species in the presence of a substrate in solution to yield a second radical ion of opposite redox character. An early observation of such chemistry was made by Chang and Bard in studies of the electrochemical oxidation of rubrene (RUB) and other fluorophores in the presence of oxalate [20]. Oxidation of oxalate, either directly at the electrode surface or by mediated oxidation by the rubrene cation, results in decomposition of the oxalate anion radical to yield CO₂ and the CO₂⁻ radical, a strong reducing agent (Eq. 5). Reaction of the CO₂⁻ radical with the RUB⁺ results in luminescence from rubrene.

The mechanism postulated by Bard involves the steps shown in Eq. 5. Subsequent studies by others have shown that this mechanism is operative for several additional reagents that decompose to yield a strongly reducing radical following one-electron oxidation. In particular, tertiary amines with a hydrogen atom in the α position undergo deprotonation following oxidation to yield a strongly reducing radical [21]. Application of these types of systems to the detection of various organic analytes is presented in Section 9.5 of this chapter.

Related chemistry has been demonstrated for reactions involving initial reduction of one species and concomitant reduction of a second species that leads to production of a strong oxidizing agent. The peroxydisulfate dianion decomposes upon reduction, to produce SO_4^- , which can annihilate with an anion radical to yield a luminescent species. White and Bard demonstrated this for reduction of solutions containing tris(2,2'-bipyridine) ruthenium(II), $[\text{Ru}(\text{bpy})_3]^{2+}$, in the presence of $\text{S}_2\text{O}_8^{2-}$ as shown below [22]:

Reactions of this type involve the oxidation/reduction of a reactive intermediate for which the one-electron redox potential may not be known (CO_2^- in Eq. 5). Determination of the free energy for formation of the emissive state requires knowledge of the potentials of both ion radicals and the energy of the emitting excited state (Eq. 2). It is, in principle, possible to find approximate values for one-electron potentials of very unstable ion radicals (e.g., the $\text{CO}_2^{-/0}$ potential of Eq. 5) by use of a series of chromophores with varying potentials for forming the excited state from the radical ion (varying $\text{RUB}^{+/*}$ potentials).

9.2.4 Chemically Induced Electron-Exchange Luminescence

This class of radiative charge recombination is very similar to the processes described in Section 9.2.3, except for the fact that generation of a transient radical ion is not necessary for initiation of the process. The free energy for generation of an excited state is possessed by a chemical substance which can be isolated and stored (as some radical ions can). The most common systems of this sort involve reaction

Scheme 1.

of organic peroxides with a luminescent “activator” molecule [23, 24]. For example, diphenoyl peroxide reacts with various aromatic hydrocarbons (i.e. pyrene, rubrene) to yield the excited hydrocarbon, benzocoumarin and CO₂. The mechanism postulated for the process is shown in Scheme 1.

Following oxidation of the aromatic hydrocarbon by the peroxide, the peroxide anion radical loses CO₂ and generates the product benzocoumarin anion radical, a strong reducing agent. Annihilation of this anion radical with the hydrocarbon cation radical results in generation of the hydrocarbon excited state. The final reaction is a radiative charge recombination and is directly analogous to the reactions in Eqs. 5d and 6d above. Koo and Schuster showed that the rate constant for the reaction correlated well with the one-electron oxidation potential of the aromatic hydrocarbon [25]. The relative yield of luminescence is insensitive to the presence of oxygen and generates emissive exciplexes when aromatic amines are used as reductants; both phenomena indicate the loss of CO₂ and back electron transfer occur within a solvent cage.

Examination of the above reaction sequence indicates that evaluation of the energy available to produce an excited state differs from the processes described in Sections 9.2.1–9.2.3. While the actual reaction to generate the excited state parallels those above, the energy available can be assessed from the free energy of thermal decomposition of the organic peroxide. Typical organic peroxides decompose to generate two carbonyl-containing species (in some cases CO₂) with heats of reaction between 2.5 and 3.9 V (55 and 90 kcal/mol). Thus, ample energy is available for generation of excited states in bimolecular reactions. While this class of radiative charge recombination reactions will not be discussed further in this chapter, the chemically induced electron-exchange luminescence mechanism may be the predominant mode of reaction in many bioluminescent systems.

9.3 Kinetic Aspects

From the above discussion it should be clear that annihilation of radical ions can result in production of several species. In the very simplest case of self-annihilation of one-electron oxidized and one-electron reduced forms of a particular species, S, three processes compete (Eq. 7).

As mentioned above (Figure 1, Eq. 2), as long as the processes shown in Eqs. 7a and 7b involve formation of the lowest-energy excited state, the relative free energies of the three processes will be $\Delta G_{\text{G}} \gg \Delta G_{\text{T}} > \Delta G_{\text{S}}$. Efficient radiative charge recombination requires that either k_{S} or k_{T} (or both) is significantly more rapid than k_{G} .

The relative rates of the reactions leading to formation of either ground-state or excited-state products can be evaluated in terms of formalisms developed by Marcus [26], Hopfield [27], Jortner [28], and others [29]. The development of the semiclassical and quantum-mechanical expressions for electron transfer are discussed in Chapters. 3–5 (Volume I, Part 1). A general expression for the rate constant of a non-adiabatic electron-transfer process is given below,

$$\begin{aligned}
 k_{\text{ann}} &= \sum_{j=0}^{\infty} F_j V^2 \left(\frac{4\pi^3}{h^2 \lambda_s k_B T} \right)^{1/2} \exp \left[-\frac{(j h \nu_v + \Delta G_q + \lambda_s)^2}{4 \lambda_s k_B T} \right] \\
 F_j &= \frac{\exp(-S) S^j}{j!} \\
 S &= \frac{\lambda_v}{h \nu_v}
 \end{aligned} \quad (8)$$

where F represents the Franck–Condon factor associated with overlap of the zeroth vibrational state of the ion pair with the j th state of the mode v (of frequency $h\nu_v$; $h\nu_v \gg k_B T$) of the recombination product (S , T , or G); λ_v is the internal reorganization energy associated with internal coordinates of the ions undergoing electron transfer, λ_s is the sum of low-frequency modes associated with the electron transfer, V is the electronic-coupling matrix element between the initial and final states, and ΔG_q is the free energy of the annihilation process that yields either an excited state or the ground state (Eq. 7). This expression indicates that, for a series of closely related electron-transfer reactions having nearly identical reorganization energies, the rate constant will reach a maximum when ΔG_q equals $\lambda_s + j h \nu_v$ (activationless electron transfer) and will then decrease as the free energy increases further (Figure 3). The region of decreasing electron-transfer rate constant with increasing exoer-

gonicity of the reaction is referred to as the Marcus inverted region. The observation of luminescence from charge recombination reactions represented an early (though indirect) verification of the existence of the inverted region [15, 18]. For the three reactions of Eq. 7, the solvent reorganization might be expected to be comparable if there are not large internal coordinate differences between the ground state and excited state products. For systems in which the product state is a locally excited state on either the electron donor or acceptor, internal coordinate distortions relative to the ground state are likely to be smaller than systems with a charge-transfer excited-state product. Nonetheless, assuming the difference in λ between reactions 7a–7c is small, the relative rate constants of the three annihilation reactions can be seen to depend on λ and ΔG as shown in Figure 3. When either ΔG_S or ΔG_T is relatively close to λ , the annihilation to yield ground state will be deep in the inverted region (since $\Delta G_G \gg \Delta G_S$ or ΔG_T) and the rate constant for formation of an excited state will be orders of magnitude larger than that for producing only ground state. However, if the free energy to produce an excited state is

Figure 3. Free-energy dependence of electron transfer reactions for case (a) λ is approximately equal to ΔG_S (or ΔG_T) and (b) where λ is closer in energy to ΔG_G .

much smaller than λ , ground-state formation can be favored (Figure 3). From Eq. 8 it can be seen that it should be possible to predict relative yields of singlet, triplet, and ground state for particular annihilation reactions if one is able to obtain reasonable estimates of the above parameters for each reaction type.

The above account, however, does not include the possibility of direct luminescence from the intimate radical-cation–radical-anion pair, a process commonly observed when the two radicals originate from different substances (i.e., not self-annihilation). As mentioned above, Weller and Zachariasse very clearly illustrated that luminescence from ion pairs (exciplexes) is significant [18, 30]. In addition, singlet emission can result from energy-deficient systems by triplet–triplet annihilation processes. The issue of charge recombination from solvent-separated and intimate ion pairs has been addressed in detail recently in the work of Gould and Farid [31, 32, 33]. In studies of cyanoanthracene anion donors and alkylbenzene cation acceptors, they were able to examine differences in charge-recombination rate constants between contact radical ion pairs (CRIPs) formed by direct excitation of the ground-state charge-transfer complex and solvent-separated radical ion pairs (SSRIPs). Significant differences were found for the electronic coupling, V , and medium reorganization energies, λ_s , of the two ion-pair types, and luminescence is only observed from the CRIPs [31a]. Figure 4 shows the free-energy dependence of return electron transfer to the ground state from contact and solvent-separated ion pairs; the smaller λ_s for the CRIPs serves to favor radiative charge recombination over decay directly to the ground state. The authors also note that electron-transfer expressions like Eq. 8 cannot be used to describe CRIPs, since results indicate that electron transfer in the CRIP case is adiabatic (strong electronic coupling).

The authors also examined the charge-transfer luminescence in detail. In the late 1980s Marcus illustrated the relationship between charge-transfer luminescence and nonradiative recombination (i.e., radiative and nonradiative electron transfer to the ground state) [34]. Marcus pointed out that the charge-transfer luminescence of a CRIP presents radiative relaxation to the ground state over a free-energy range that is analogous to the normal and inverted regions. Thus, the charge-transfer emission can be fit by a series of Gaussian functions with spacings between the maxima of $h\nu$. The width of each Gaussian component depends on λ_s and the magnitude of each component is given by the relative Franck–Condon factors. The significance of this is that all of the adjustable parameters required to predict the rate constant of the nonradiative charge recombination process are obtained [32]. Gould and coworkers illustrated the validity of this approach by taking parameters from fits of charge-transfer luminescence of 1,2,4,5-tetracyanobenzene/hexamethylbenzene complexes in several solvents, using the parameters to calculate rate constants for nonradiative electron transfer and showing that the values obtained correlated well with experimental rate constants [35]. Like the earlier results of Bard, indicating excimer formation is more likely to result from annihilation of two triplets than from direct excitation of the chromophore, the work of Farid and Gould shows that vast differences exist between recombination processes of contact and solvent-separated ion pairs.

Localized fluorescence that results from cross-electron-transfer reactions can occur by direct singlet formation or by reaction to yield triplets that annihilate to

Figure 4. Free-energy dependence of return electron transfer for contact ion pairs (A^-D^+) and solvent-separated ion pairs ($A^-(S)D^+$) for recombination of dicyanonaphthalene anions with alkylbenzene cation radicals. produce the fluorescent excited species (Eq. 1a, Eq. 3). Recently, Wightman and coworkers used high-frequency generation of radical ions at microelectrodes to explore the dynamics of luminescence evolution in systems containing DPA and one of a group of electron donors [36]. The free energies for the reaction of DPA^+ with the donor anion radical ranged from +3.24 V to +2.41 V. Since the energies of the excited DPA singlet and triplet are 3.06 and 1.8 V, respectively, some of the reactions were energy-sufficient and others generated fluorescence by triplet-triplet annihilation. Observing the intensity-time dependence of the electrochemically generated luminescence in the 0–500 μs time regime, the authors were able to unambiguously determine the chemistry leading to DPA fluorescence by determining the reaction order for fluorescence onset and the degree of quenching by radical ions in solution. Particularly interesting was the observation that reaction of DPA^+ with the naphthyl phenyl ketone anion (NPK^-) ($E_{\text{ann}} = 3.01$ V) could occur by both mechanisms and that the predominant path depends on the concentration of DPA.

The question of the free-energy dependence of heterogeneous electron-transfer reactions at liquid-liquid interfaces was addressed by Bard and coworkers. They ex-

aminated radiative charge recombination at the water–benzonitrile interface to illustrate inverted region behavior in this type of heterogeneous electron transfer [37]. The generation of DPA^+ (and $[(\text{bpy})_3\text{Ru}]^{3+}$ and thianthrene cation) in the vicinity of a benzonitrile/aqueous $\text{C}_2\text{O}_4^{2-}$ interface resulted in luminescence, presumably by a mechanism analogous to Eqs. 5a–c. The reactions paralleling Eqs. 5b and 5d are heterogeneous; direct recombination of the cation radical and CO_2^- to yield ground-state products cannot compete effectively with formation of the excited state. Thus, they concluded the highly exoergic heterogeneous reaction to form ground-state products is in the inverted region.

9.4 Experimental Considerations: Techniques and Molecular Systems

9.4.1 Generation and Characterization of Reactive Species

Early studies of radiative charge recombination processes made use of chemical oxidation and reduction to create the reactive radical ion species. Despite the limitation of the use of chemically stable radical ions, a significant body of literature developed that discussed radiative charge recombination for cross-electron-transfer reactions. In particular, many studies involved reactions of organic radical anions with amine cation radicals [5, 15, 18, 19].

Paralleling this work was a growing body of literature illustrating electrochemical methods for the generation and investigation of luminescence by annihilation of radical ions produced either by simultaneous (two-electrode) or sequential (one-electrode) processes. Electrochemical methods made it possible for the reactive species to be formed in a controlled fashion, for the generation of either pulses of emitted light or continuous luminescence. Faulkner, Bard, and coworkers give overviews of experimental methods in excellent reviews [9, 11, 38].

Pulsed electrode techniques

One approach for obtaining electrogenerated chemiluminescence (ECL) involves sequential oxidation and reduction of a species capable of exhibiting luminescence. This is most commonly accomplished by sequential potential steps, as shown in Figures 5 and 6 [6, 11, 39]. Initial reduction of substrate for a period of time t_f results in formation of the anion radical extending some distance from the electrode surface as shown in Figure 5. At time t_f , the potential is stepped to a value capable of oxidizing the substrate (oxidation of both S and S^- to S^+ will occur) and is held at that value for a time t_r . Luminescence will be observed if the potential is switched and will continue until no S^- remains to react with S^+ (or, if t_r is short relative to t_f , until all S^+ is consumed), as shown in Figure 6. Figure 5 also shows the concentrations of S , S^- , and S^+ as a function of the distance from the electrode at some time during the oxidation of S . This figure illustrates that a reaction plane is established where S^- and S^+ annihilate and luminescence occurs. With increasing time

Figure 5. Concentration-distance profiles: (A) following reduction of S to S⁻ and (B) after subsequent change in potential to oxidize S to S⁺. The dotted line represents the plane where annihilation of S⁺ and S⁻ occurs.

($t > t_f$), the plane where luminescence is observed moves away from the electrode and the luminescence intensity decreases as the available S⁻ is depleted.

Analysis of the decay of luminescence intensity with time has been shown to be related to the mechanism of the annihilation process (i.e., direct fluorescence from singlets or luminescence resulting from triplet-triplet annihilation). Feldberg developed simulation techniques for intensity-time profiles from potential step experiments, relating the emission rate (photons/s) to the total redox rate N (moles/s) [40].

$$I = \phi_F \eta^* N \quad (9)$$

The parameters ϕ_F and η^* represent the fluorescence quantum yield of S^{*} and the efficiency of emitting excited states being produced in the charge recombination reaction [$k_S/(k_S + k_T + k_G)$, from Eq. 7]. Feldberg determined that a linear relationship exists between ω , a dimensionless rate parameter proportional to the emission intensity [$\omega = (It_f^{1/2})/(\phi_F AD^{1/2} C)$; A = electrode area, D = substrate diffusion coefficient, C = bulk concentration of S], and $(t_r/t_f)^{1/2}$ (Eq. 10).

$$\log(\omega) = 0.7 + \log(\phi_F \eta_*) - 1.45(t_r/t_f)^{1/2} \quad (10)$$

Figure 6. (A) Potential sequence for generation of ECL by double potential step methods and (B) the intensity-time profile resulting from the potential sequence of (A).

The constants of the equation were obtained from simulations and the process applies only to generation of singlet excited states at diffusion-limited annihilation rates. Nonetheless, the expression provided an experimental approach for determining efficiencies of the production of emitting excited states in annihilation reactions. Simulations for systems that react via triplet formation and subsequent triplet-triplet annihilation were also developed [40b] and they illustrated that the two mechanisms can be distinguished by analysis of intensity-time profiles.

With the advent of rapid-scan and high-frequency pulse methods, more direct approaches for evaluating annihilation mechanisms and dynamics have been developed. Early work of van Duyne, using triple potential steps with very short step times, allowed estimation of the annihilation rate constant for DPA anion and cation radicals [29]. More recently, Wightman and coworkers have used multicycle generation of ECL at microelectrodes to determine annihilation rate constants and ECL efficiencies [41, 42]. Figure 7 shows the normalized ECL intensity from DPA at a 1- μm Pt disk as a function of time (t/t_r) at different oscillation frequencies. The intensity increases rapidly after the potential is switched, and then decays as the reactants are depleted. As the oscillation frequency is increased, the annihilation occurs closer to the electrode surface, the intensity-time profile broadens and

Figure 7. ECL intensity from 0.38 mM DPA in CH_3CN containing 0.1 M tetrabutylammonium hexafluorophosphate at a $1 \mu\text{m}$ Pt disk (—) and simulations of the profiles, assuming diffusion-limited annihilation of DPA^+ and DPA^- . From Collinson, M. M. et al., *J. Phys. Chem.*, **1994**, 98, 11942, with permission from the American Chemical Society.

the experimental intensities are smaller than those expected from simulations. The broadening of the emission profile with time indicates the evolution from diffusion control to kinetic control in the experiment, and provides data that can be simulated to yield ion annihilation rate constants. The decreased intensities have been attributed to quenching by the electrode [43, 44]. As mentioned in Section 9.3 above, this technique also provides a direct approach that serves to distinguish energy-sufficient and energy-deficient processes leading to fluorescence by ECL. Finally, distinct interference patterns have been observed in the ECL intensity–time profiles obtained at frequencies between 2 and 20 kHz for millimolar solutions of substrates [45]. On these timescales, the emission plane is at a distance from the electrode comparable to the wavelengths emitted by chromophores such as DPA and $[(\text{bpy})_3\text{Ru}]^{2+}$. Fourier transforms of these interference patterns produce frequency-domain spectra of the emitting chromophores. This is an interesting verification of the predicted

oscillations in chromophore emission intensity with distance from metallic electrodes [43, 44].

Steady-state electrochemical methods

The most useful electrochemical way to generate radical ion species for steady-state ECL measurements is rotating ring-disk voltammetry, RRDE. While the technique requires two potentiostats and the ring-disk electrodes, the apparatus is sold commercially and both instrumental and conceptual aspects of the technique have been described in detail by Faulkner and Bard [11]. Briefly, ring-disk electrodes consist of a disk electrode and a concentric ring electrode that is electrically insulated from the disk. The potential at each electrode can be independently controlled so that one reactant can be generated at the disk and the other at the ring. When the ring-disk electrode is potentiostatted and rotated, lamellar flow established at the planar disk electrode transports solution from the disk to the ring. In a typical RRDE experiment, annihilation of cation and anion radicals occurs at the inner ring surface and a thin ring of luminescence is generated. This steady-state experiment can be used to measure ECL quantum yields; because annihilation reactions are generally diffusion limited and an excess of the oppositely charged radical ion is generated at the ring electrode, essentially all the ion produced at the disk is trapped and thus the number of annihilations per second is given by $N = i_{\text{disk}}/n\mathfrak{F}$. If an RRDE system is calibrated to yield absolute values of the emission rate, ECL quantum yields can be determined [16, 46].

RRDE experiments are also useful for the examination of systems where multi-electron oxidation or reduction reactions are possible. An example is shown in Figure 8 for the reduction of DPA at the disk while TMPD^+ is steadily generated at the ring [46]. The emission intensity increases as the DPA is reduced at -1.8 V;

Figure 8. RRDE experiment illustrating the disk current and emission intensity as a function of the disk potential in a cell containing TMPD and DPA. The ring current is fixed at $+0.35$ V to generate TMPD^+ and the disk potential is scanned. From Maloy and Bard, *J. Am. Chem. Soc.*, **1971**, 93, 5968, with permission from the American Chemical Society.

however, the second reduction of DPA (to produce DPA^{2-}) leads to a decrease in the ECL intensity, apparently because the dianion is highly reactive and does not survive to reach the ring.

9.4.2 Molecular Systems

This section is intended to provide representative examples of particular molecular systems that have been well studied and are known to undergo either self-annihilation or cross-electron-transfer reactions to generate luminescence. The structures of organic species commonly observed to participate in radiative charge recombination reactions are shown in Figure 9 (either lumophores or ancillary reactants). Tables 1 and 2 provide data for inorganic and organic systems that undergo self-annihilation

Table 1. Inorganic complexes exhibiting ECL via self-annihilation.

to generate luminescence. The one-electron potentials for reduction of the cation radical (or oxidized metal complex) and reduction of the compound are presented along with the emission maxima and luminescence quantum yield (not the radiative charge recombination yield). In Table 1, only a few derivatives of $[(bpy)_3Ru]^{2+}$ are presented; however, this class of chromophores makes up by far the largest and most widely studied class of ECL active molecules, and numerous applications making use of Ru^{II} complexes have been developed (vide infra). Luminescence of all Ru^{II} and Os^{II} diimine complexes originates from a triplet metal-to-ligand charge-transfer (MLCT) transition. The precise energy of the singlet MLCT state is not known, but even if annihilation could yield the singlet state, the intersystem crossing efficiency is unity [47]. The palladium(II) porphyrin, $Pd(TPP)$, exhibits only phosphorescence following reaction of $[Pd(TPP)]^+$ and $[Pd(TPP)]^-$, despite the fact that the reaction is of sufficient energy to generate the singlet, and fluorescence is observed upon photoexcitation [48]. Both the one-electron oxidized and one-electron reduced forms of $[Pt_2(P_2H_2O_5)_4]^{4-}$ are unstable; the oxidized complex disproportionates at diffusion-limited rates. Nonetheless, ECL has been observed for this strongly luminescent chromophore. Nocera and coworkers reported ECL for Mo and W clusters, including luminescence from cross-reaction of the oxidized Mo complex and reduced W complex.

The instability of either the radical cation or the radical anion of such systems limits the number of organic systems studied by direct oxidation and reduction of a chromophore. A large number of experiments have been performed on DPA and rubrene for which reversible one-electron oxidation and reduction is possible. These systems represent standards for the development of new analytical methods. For example, absolute ECL quantum yield measurements were made by Bezman and Faulkner using rubrene as substrate [49]. More recently, DPA has been used extensively in ECL investigations involving high-frequency voltage oscillations, which include intriguing observation of individual chemical reactions in solution [50]. With the development of rapid-scan (high-frequency potential step) methods, a broader range of organic systems can be investigated.

A very large number of radiative charge recombination processes involve annihilation of known cation radicals and anion radicals, CIEEL processes, or reactions involving an ion radical and a reactive substrate which will decompose to a radical ion. Table 3 provides a very brief list of well-studied cases. The literature is extensive and readers are referred to earlier reviews of this topic [15, 18, 23, 30].

9.5 Applications

9.5.1 Sensors for Organic Substrates Employing $[(bpy)_3Ru]^{2+}$ and Derivatives

There has been rapidly growing interest in the use of ECL systems in sensor development. ECL detection of analytes can be performed with the use of uncomplicated instrumentation and inexpensive materials. The observation of luminescence, par-

ticularly in the absence of an excitation light source, affords high sensitivity and a broad dynamic range. Since annihilation reactions often occur at near-diffusion-limited rates, signal onset and equilibration are generally limited by factors other than reaction dynamics in ECL systems. Several comprehensive reviews of analytical applications of ECL have been published in recent years [12, 51, 52] and the systems discussed below will provide illustrative examples and report some recent developments.

A vast number of ECL systems are based on luminescent Ru^{II} complexes, and the most widely studied is [(bpy)₃Ru^{II}]²⁺. Luminescence from this chromophore is from a metal-to-ligand charge-transfer triplet state, ³MLCT. This state can be created by several mechanisms, as discussed in Section 9.2.3 [52]. One approach involves reduction of the complex in the presence of persulfate anion; reduction of persulfate results in formation of SO₄⁻, a strong oxidant, which reacts with [(bpy)₃Ru]⁺ to yield the ³MLCT state. However, persulfate is the only species known to react in this way with the complex and no applications currently exist [22]. Of greater importance are systems in which the emitting species can also be obtained by oxidation of [(bpy)₃Ru]²⁺ in the presence of a substrate that generates a strong reductant following a one-electron oxidation. Analytical applications are given below.

Detection of aliphatic amines

In 1987, Noffsinger and Danielson reported the generation of ECL from the reaction of [(bpy)₃Ru]²⁺ with aliphatic amines, proposing the following mechanism

[21];

Leland and Powell [53] also studied ECL obtained from reaction of $[(\text{bpy})_3\text{Ru}]^{3+}$ with tripropylamine. There is an inverse relationship between the first ionization potential of the amine and ECL intensity and therefore $[(\text{bpy})_3\text{Ru}]^{2+}$ ECL intensity can be ordered as follows: tertiary > secondary > primary.

Bioorganic applications

With the knowledge that ECL can be generated by alkyl amines, Bobbitt et al. [54] have reported the detection of amino acids by $[(\text{bpy})_3\text{Ru}]^{2+}$ ECL. When capillary electrophoresis is employed in the separation, the presence of various amino acids, in particular proline and leucine, can then be detected directly by reaction with $[(\text{bpy})_3\text{Ru}]^{3+}$ generated in situ with up to a femtomolar sensitivity.

Jameison et al. [55] demonstrated the quantitative ECL detection of β -nicotinamide adenine dinucleotide (NADH) and the phosphate NADPH. They proposed the following mechanism, which involves direct oxidation of the NAD(P)H and the Ru complex at the electrode:

The intermediate, NAD^\bullet or NADP^\bullet , is a radical on the nicotinamide that can annihilate with $[(\text{bpy})_3\text{Ru}]^{3+}$. This system is significant, because the activity of any enzyme that produces or consumes either NADH or NADPH can be directly monitored by ECL.

Another interesting application involves use of ECL in the detection of pathogenic bacteria that produce β -lactamases, enzymes that aid the bacteria in resisting the toxic effects of clinically administered β -lactam antibiotics such as penicillins. They function by hydrolytically opening the cyclic amide of the antibiotic, thereby rendering it harmless to the bacteria (Figure 10). Liang et al. have developed a method of indirectly screening bacteria for the presence of β -lactamases by utilizing

Figure 10. The hydrolysis of penicillin by β -lactamase.

the ability of β -lactam antibiotics to act as the amine-containing reductant in the $[(bpy)_3Ru]^{2+}$ ECL reaction [56].

In related work, Dong and Martin developed an assay that detects the catalytic activity of the enzymes pig liver esterase and porcine kidney leucine aminopeptidase by using substrates which have been labeled with metal-binding ligands [57]. The enzymes catalyze changes in the substrates that affect their ability to bind to non-luminescent Ru complexes to form mixed-ligand complexes capable of ECL.

Analysis of pyruvate can also be accomplished by ECL of Ru^{II} complexes. Since Ru^{III} bipyridine complexes are not strong enough oxidants to directly oxidize pyruvate (to generate a strongly reducing radical species following decarboxylation), Ce^{3+} is added. By the application of a higher electrode potential, Ce^{4+} is generated, which can mediate the oxidation of pyruvate to form intermediates which can reduce $[(bpy)_3Ru]^{3+}$, ultimately leading to luminescence from the Ru^{II} bipyridyl complex [58].

Immunoassays and DNA probe assays

Blackburn et al. reported the first use of ECL detection for the development of immunoassays and DNA probe assays [59, 60]. By modification of one of the bipyridyl ligands of $[(bpy)_3Ru]^{2+}$ with a *N*-hydroxysuccinimide, a reactive species that readily labels proteins and nucleic acids is obtained. An immunoassay device was developed by IGEN, Inc [61]; this device employs magnetic beads chemically modified in a variety of ways to promote association of immune complexes labeled with ECL-active Ru^{II} . Figure 11 illustrates various modes of association of antigen/antibody complexes and other biomolecules with magnetic beads. The beads are drawn to an electrode surface by magnetic interaction and ECL is induced from the Ru^{II} complex bound to the beads by a mechanism involving reaction of electro-generated Ru^{III} with a tertiary amine [62]. ECL methods show promise for widespread use in immunoassays since the technique offers very low detection limits and eliminates the use of radioactive isotopes employed in many current methods. The Ru labels are versatile and long-lived, and even multiple labels do not interfere with antibody immunoreactivity.

The magnetic bead / ECL approach has also been used in DNA-probe assays. Perkin Elmer Corporation has developed an ECL-based assay for post-PCR product detection [63]. (Figure 11). The method allows PCR product identification following fewer PCR cycles than other available analytical methods.

Another novel approach to identification of particular DNA fragments by ECL

Figure 11. Modes of association of antigen/antibody complexes and other biomolecules with magnetic beads.

was recently presented by Xu and Bard [64]. The approach was to modify a Au electrode with difunctional hydrocarbon having a thiol to bind to the gold surface and a phosphonic acid moiety to ion pair with Al^{3+} in solution. The resulting modified electrode efficiently binds the phosphate group of DNA single strands (i.e., poly-dC). Exposing this electrode to $[\text{Ru}(\text{bpy})_3]^{2+}$ -labeled single strands with the complimentary sequence (i.e., poly-dG), results in ECL from the surface-bound Ru^{II} complex in the presence of tripropyl amine. The approach requires complete surface coverage by the unlabeled single strand and stability of the surface ensemble to temperature cycling required in the hybridization process.

Immobilized $[(\text{bpy})_3\text{Ru}]^{2+}$ and derivatives

There has been significant effort to develop analytical systems involving ECL-active Ru^{II} diimine complexes immobilized on electrode surfaces [65, 66]. Electrode-bound Ru^{II} complexes immobilized in Nafion films by electrostatic binding have been used in flow-injection analysis of oxalate, alkyl amines, and NADH [67]. Martin and Nieman have also employed electrode-bound Ru^{II} bipyridyl complexes in the analysis of glucose by detecting NADH produced in oxidation of glucose by glucose dehydrogenase [68]. In addition, an extremely sensitive fiber-optic-linked ECL probe for oxalate was reported by Egashira and coworkers [69].

Figure 12. Proposed ECL mechanism of luminol.

9.5.2 Sensors Employing Other ECL Chromophores

Luminol-based detection of molecules

Often conventional chemiluminescence reactions can be initiated electrochemically. The luminol reaction has been studied in detail and the mechanism of the ECL reaction is believed to be similar to that of chemiluminescence. As shown in Figure 12, the luminol ion undergoes a one-electron oxidation to yield a diazaquinone, which reacts with peroxide (^-OOH) to give the excited 3-aminophthalate, which has an emission maximum of 425 nm. This reaction is particularly versatile and has been utilized in a variety of ECL assays, many of which have been summarized by Knight [12]. The luminol ECL reaction can be used for the determination of any species labeled with luminol derivatives, hydrogen peroxide, and other peroxides and enzymatic reactions which produce peroxides. A few of them are briefly described below.

Sekura and Terao reported a luminol-based ECL sensor for lipid hydroperoxides, which are of great importance since they are involved in the regulation of prostaglandin biosynthesis, which in turn can lead to cancer development, aging, and other pathological conditions [70]. In this method, there are two approaches for generation of ECL. By the application of potentials between 0.5 and 1.0 V, luminol is oxidized to a diazaquinone which reacts with free lipid hydroperoxide to yield

luminescence as in Figure 12. When the applied potential is greater than 1.0 V, both luminol and the lipid hydroperoxide are oxidized electrochemically and a more complicated emission occurs by the reaction of the diazaquinone with the oxidized product of lipid hydroperoxide.

Marquette and Blum have reported a luminol-based fiber-optic biosensor for glucose and lactate [71]. In this method, glucose oxidase or lactate oxidase is immobilized on preactivated membranes. Substrates present in solution, glucose or lactate, are oxidized by the respective enzyme, producing hydrogen peroxide. Luminol, which has been previously oxidized at a glassy carbon electrode, reacts with hydrogen peroxide, producing an ECL signal.

Other systems

There is a variety of analytical applications that involve electrochemical generation of luminescence in systems for which the chemistry is not clearly understood. A few are mentioned here.

A novel ECL assay for the determination of 2,4- and 3,4- diaminotoluene (DAT) isomers is based on reaction of these molecules with Au^+ and Cu^{2+} , respectively, in aqueous solution under oxidizing conditions in buffer-containing tripropylamine [72]. Luminescence is observed upon potential ramping from 0 to +2.8 V. The nature of the emitting species was not specified, but could involve a charge-transfer excited state of the metal complex with DAT or an oxidized form of DAT. DAT isomers were screened for ECL enhancement against 32 metals; the apparent specificity of Au^+ for 2,4-DAT and Cu^{2+} for 3,4-DAT is believed to be linked to the radii of each ion. This ECL approach could lead to applications in the determination of some aminoaromatics from degradation of explosives (e.g., TNT) as well as detection and quantification of various transition metals in water supplies.

Chen et al. characterized ECL from indole and tryptophan in the presence of hydrogen peroxide under oxidizing conditions. In both cases, there is only tryptophan or indole, electrolyte, and H_2O_2 in the cell. A triangular pulse voltage was applied (1.0 V) to oxidize tryptophan or indole. Tryptophan and indole are both very weakly electrochemiluminescent in the absence of H_2O_2 , but with peroxide, the ECL signal is enhanced. The process is believed to go through a dioxetane intermediate obtained after one-electron oxidation of the substrate. The presence of seventeen other amino acids (in excess) did not interfere in the determination of tryptophan, making the method remarkably selective.

Egashira et al. observed ECL from various hydroxyl compounds; this led to the development of alcohol and sugar sensors [73, 74] ECL is observed upon voltage-cycling of basic aqueous solutions of various sugars and simple vicinal alcohols between +1.4 and -1.2 V (vs. Ag/AgCl). While the mechanism is not clear, the authors state that aldehyde excited states may be formed; no spectral data is given as the emission is very weak.

A completely new source of electrochemiluminescent compounds may have been discovered recently. Weak luminescence was observed from fluids extracted from tunicates, a type of marine invertebrate, and synthetic tunichromes (**1**; chromophore in the tunicates) upon oxidation [75]. There was a 10-fold enhancement of ECL

when the synthetic analogs of the tunichromes were complexed to Hg^{2+} . The mechanism of the luminescent enhancement is not clear.

9.5.3 Device Applications

Electroluminescent displays

The application of radiative charge recombination with the greatest commercial potential is the development of electroluminescent devices based on organic light-emitting diodes (OLEDs). The typical device consists of a sandwich arrangement of materials: an optically transparent electrode, a hole-conducting layer, a luminescent chromophore, an electron-conducting layer and a second electrode. In some devices, the hole or electron carrier may also be the luminescent chromophore and even simpler devices exist, with a single organic thin film sandwiched between two electrodes. Radiative charge recombination in solid-state devices is complicated in several ways unique to the medium. The additional issues that arise involve rates of charge transport in the electron and hole carriers, excited-state quenching in the solid state and interactions of excited states with the charged electrodes. This area has been the focus of a tremendous amount of research directed toward understanding the fundamental factors important in the operation of electroluminescent devices. Several recent reviews provide excellent overviews of these topics and even a superficial discussion of organic light-emitting displays is beyond the scope of this chapter [76, 77].

However, the link between electrogenerated chemiluminescence in solution and electroluminescence is obvious. In recent work of Armstrong, Wightman, and coworkers, the detailed aspects of ECL generation from components widely used in the construction of organic organic LED's is discussed [78]. Some of the examined systems had multiple radical ion recombination reactions and potential-emitting excited states; the results showed that emission always occurred from a single emitting excited state. In addition, electroluminescent devices containing $[(\text{bpy})_3\text{Ru}]^{2+}$, one of the most widely studied ECL-active molecules, as the emitting chromophore, have been produced [79, 80, 81].

Laser action driven by ECL

ECL for laser applications has been investigated because of the advantages it may have over conventional dye lasers. A laser operating by ECL would not require an additional pump laser, and enhanced power, tunability and range of available wavelength are additional factors. While the pumping rate achieved by ECL previously has been two orders of magnitude lower than the optimal, Horiuchi et al. have reported a device structure designed to enhance the ECL efficiency and realize laser action driven by ECL [82].

Scanning electrochemical microscopy

Light emission by ECL at scanning electrochemical microscope (SECM) tips is also under current development [83]. Visible light is generated at the SECM tip by ECL as the tip is moved in the vicinity of insulating and conductive substrates. ECL intensity decreases with both insulating and conductive substrates as the tip-substrate distance decreases. Although the resolution is still poor, the technique shows potential for applications in the studies of the kinetics and mechanisms of co-reactant ECL reactions.

9.6 Summary

The thrust of this chapter has been to provide a brief overview of this fascinating area, from the essential theoretical framework provided by electron-transfer theory to the array of potential novel device applications. From early studies of radiative charge recombination, experimental approaches developed greater sophistication and the range of chemical reaction types expanded. The ability to generate luminescence by electrochemical excitation presents a rich array of potential device applications and the future of research in this area is certainly bright.

10 Electron Transfer Reactions in Organic Chemistry

Stephen F. Nelsen

10.1 Introduction

Reactions of organic compounds involving electron transfer are so common that this review cannot even attempt to be comprehensive, and I apologize in advance to the many people whose work has been omitted. Pross and Shaik especially emphasized the similarity between two-electron polar processes and single-electron-transfer processes at the level of consideration of reaction-coordinate diagrams [1]. Most bond-shift reactions can be postulated to involve sequential single-electron-transfer steps, and the single-electron-transfer formalism has been extended to a very wide range of chemistry [2]. Especially Ashby's group reformulated several reactions involving organic compounds that are usually considered to be two-electron bond-shift reactions as single-electron-transfer reactions, including Grignard additions and metal hydride reductions [3]. Some examples of these reactions very likely do involve single-electron transfer, but others may well not. Ashby [3a] has responded to criticism of the ring-opening methodology that was used as evidence for single-electron-transfer reactions in some cases [3b]. This chapter will focus on reactions that unarguably involve single-electron-transfer steps. Schmittle and Burghardt have provided a very useful review of radical cation reactions [4].

Reactive radical ions may often be generated by electrochemistry and/or photochemistry either in addition to, or instead of, independently prepared redox reagents that cause electron transfer to occur spontaneously, using thermal excitation energy. This makes it impractical to separate the types of chemistry initiated by electron transfer according to the mode of radical ion generation. Electron loss (or gain) by a neutral diamagnetic organic molecule (by far the most common kind), produces a radical cation (or anion), from loss of an electron from the highest occupied molecular orbital (or gain of one in the lowest unoccupied molecular orbital). This can result in very large changes in bond strength, frequently initiating cleavage and/or addition reactions. Nicholas and Arnold gave an important early discussion of the relationship between solution- and gas-phase measurements of the ease of electron

**1**

and proton transfer and bond strength. They used thermodynamic cycles to demonstrate the great acidity of toluene radical cation, and, in general, the bond-weakening that accompanies electron loss or gain [5]. Thermodynamic cycles including redox potentials and pK_A values are now often used for estimating bond dissociation energies, especially by Bordwell and coworkers [6]. As an example of bond weakening, the central C–C bond cleavage reactions of the radical ions derived from 4,4'-substituted bicumyls (**1**) have especially been studied by Maslak and coworkers [7]. Both the radical cations and radical anions of **1** have so much weakening of the central bond that spontaneous cleavage to cumyl radicals and cumyl cations or anions occurs, and substituents X and Y have been varied to bring the rate constants for cleavage into convenient ranges for measurement. Various 4'-substituted 4-Me₂N **1**^{•+} radical cations generated by chemical or photolytic oxidation have free energies of activation for central bond cleavage that average 23 kcal/mol lower than the neutral compounds, and the rate constants show little variation with solvent because of compensating enthalpy and entropy effects. The radical anions of the corresponding 4-NO₂-substituted systems average 12 kcal/mol lower free energies of activation than their neutral compounds. Later work uses radical cations generated by photo-electron transfer with tetranitromethane [7d] or chlorinated quinones [7e] to study reactions within contact ion pairs generated by irradiation into the charge-transfer band, and in solvent-separated ion pairs generated by irradiation into the quinone.

10.2 Inner- and Outer-Sphere Electron Transfer Reactions

Taube used the term inner-sphere for electron transfer between inorganic redox centers that were connected by a bridging ligand at the transition state [8], and it meant the same thing to Ebersson in 1982 [9]. Here electron transfer occurs within bonding distances between the reactants, through the first coordination sphere of the metal, and ligand transfer occurs simultaneously with electron transfer [10], (so the process might be termed L[−] transfer as well as e[−] transfer). Outer-sphere then referred to electron-transfer transition states that did not transfer a ligand along with the electron, that is, ones that lacked significant bonding between the partners, and kept the inner coordination shells for the participating metal intact in the transition state. Outer-sphere reactions are the type of electron transfer with which Marcus- and related electron-transfer theories deal (see Volume I, Part 1, Chapter 3).

The situation is somewhat different for many main-group compounds, where “three-electron σ -bonded” dimeric radical ions often exist. Thus, instead of being the transition state for electron transfer between the components, a bonded, inner-sphere species is often lower in enthalpy than the separated components, and an intermediate for electron transfer between them. Occurrence of 3e- σ -bonded species was pointed out by Pauling almost 70 years ago [11a], and examples with small substituents have been studied computationally more recently [12]. Examples in several systems are experimentally established [13], both for anions like $[\text{Cl} \cdot \cdot \text{Cl}]^-$ [14a] and $[\text{RS} \cdot \cdot \text{SR}]^-$ [14b–d]) and for cations like $[\text{R}_2\text{S} \cdot \cdot \text{SR}_2]^+$ (both in solution [13, 15a–b] and in the gas phase) [15c] and special examples of $[\text{R}_3\text{N} \cdot \cdot \text{NR}_3]^+$ [18]. In valence-bond language these species are stabilized by having resonance structures with charge on either group [11a], and in molecular orbital terms, by having two bonding electrons and only one antibonding electron in a weak σ bond, formed by end-on overlap of p-rich orbitals centered at the two heteroatoms [11b]. Only a few examples of unsymmetrical or neutral systems are well characterized, such as $\text{R}_2\text{S} \cdot \cdot \text{SR}$ [16], and Clark pointed out that the 3e- σ bond strength decreases regularly as the difference in ionization potential of the components increases [12a]. The 3e- σ -bonded radical cations can also rearrange to unsymmetrical hydrogen-bonded species that are intermediates in hydrogen-transfer reactions [12d], and the presence of both species is indicated by tandem mass spectroscopy experiments on methyl chloride [17]. Asmus especially studied geometry effects on the strength of 3e- σ bonds in $[\text{R}_2\text{S} \cdot \cdot \text{SR}_2]^+$ through studies of the absorption spectra of both acyclic and cyclic disulfides [13a, 14b]. Alder examined $[\text{R}_3\text{N} \cdot \cdot \text{NR}_3]^+$ in many examples of medium-ring bridgehead diamines [18a], finding that the triply tetramethylene bridged species **N[444]N**, which has the nitrogens pyramidalized inward, as indicated, gives the most persistent radical cation of all. **N[444]N** is isolable in all three oxidation states, with N–N distances of 2.806(6) Å (neutral), 2.295(10) Å (1+) and 1.532(6) Å (2+). Although **N[333]N**⁺ is also isolable, examples with different sized bridges, which cause the neutral form to prefer conformations with lone pair axes that are not collinear, are much less stable. When the third ring is changed to two methyl groups in **MeN[44]NMe**⁺, the radical cation formed by reduction of the dication only lasts milliseconds at room temperature; this implies that the $[\text{R}_3\text{N} \cdot \cdot \text{NR}_3]^+$ bond strength is about 15 kcal/mol, because bond cleavage to give the amine radical cation that is unstabilized by a 3e- σ bond is the rate-determining step for decomposition; the cleaved material undergoes rapid intramolecular hydrogen transfer. Oxidation of neutral diamines usually does not lead to 3e- σ -bonded species unless the nitrogens are pre-organized by their substituents to have the nitrogens rather close, and to also have their lone-pair orbital axes nearly collinear in the neutral form [18]. For example, oxidation of neutral **MeN[44]NMe** does not produce the 3e- σ -bonded cation. Vogel and Gerson have shown that the unsaturated bis(aza)-bridged cyclotetradecaheptaene system of **2** provides a rigid framework that allows the N,N'-dimethyl-substituted 3e- σ bonded compound (**2**⁺) not only to be produced from the neutral species, but to be isolated [19]. Quinuclidine gives the dimer radical cation **3** upon oxidation at low temperature [20], which we presume occurs because its bicyclic structure precludes the rapid hydrogen-atom transfer that rapidly destroys most intermolecular amine–amine radical cation pairs.

A source of confusion is that inner-sphere means different things to different people. In ET theory discussions, which overwhelmingly focus on Taube outer-sphere reactions, inner-sphere effects (sometimes used interchangeably with inner-shell) refer to large λ_{in} values, as in McLendon's definition, "changes in bond angles and bond lengths in the reactant and product molecules themselves" [21a]. Thus, for Marcus theory discussions, inner-sphere effects refer to Taube outer-sphere reactions that are slower than "expected" because the transition metal coordination complexes that are implicitly considered as the standard reactions have vanishingly small λ_{in} , and λ_{out} is expected only to depend on molecular size. As a radical ion becomes more stabilized by delocalization, the localization required to produce a $3e$ - σ -bonded dimer radical ion makes it less likely that this species will be an intermediate in electron transfer. A large inner-sphere effect in the sense of a large λ_{in} value does not necessarily promote inner-sphere electron transfer in the Taube sense. Although hydrazine radical cations have exceptionally large λ_{in} values (see Section 10.8.1), they undergo electron transfer by a Taube outer-sphere mechanism, because they enjoy more π -stabilization by delocalizing the charge over both nitrogens than they would gain by delocalizing charge in a σ -bond of a dimer radical cation. The charge-localized trialkylamine radical cations usually undergo hydrogen transfer more rapidly than they do electron transfer with their neutral forms, so "self" electron transfer is not observed, although, as pointed out above, **3** is an observed intermediate in self-ET of quinuclidine.

Especially Eberson and Shaik [22] and Kochi [23] have introduced a third different usage for inner-sphere, in attempting to more carefully consider Taube outer-sphere reactions. "Its meaning [inner-sphere] has been extended to encompass ET between D[onor] and A[cceptor] that are strongly coupled due to mutual interpenetration of their coordination spheres" [23a]. Electronic coupling between the components of an electron-transfer reaction is quantitatively measured by the parameter H_{ab} (also called J , V , and β , among other designations). Eberson and Kochi both use the criterion that, when H_{ab} is >1 kcal mol⁻¹, a reaction should be classified as inner-sphere. However, Marcus- and other electron-transfer theories do not assume that H_{ab} is small, although its size relative to λ is important. Thus, discussions of electron-transfer theory do not use inner-sphere to refer to the size of H_{ab} , instead employing the terms adiabatic and non-adiabatic for reactions having high and low H_{ab} relative to λ . Different limiting-rate equations are needed for adiabatic and non-adiabatic reactions [21]. An H_{ab} of 1 kcal/mol lies between these limits for most cases, so $H_{ab} = 1$ kcal/mol does not appear to constitute a borderline between different regions in terms of modern ET theory. Savéant considers inner- and outer-sphere as separate, well-defined reactions that can be in competition, referring to the

Taube usage of these words. Both Shaik and Fawcett discuss the inner- and outer-sphere possibilities as two ends of a mechanistic continuum, which is certainly true if by these terms one means the size of H_{ab} [24]. Other terms that might be less confusing are also used to make the distinction between negligible and non-negligible electronic interaction at the ET transition state: outer-sphere in the Ebersson-Kochi sense has also been called nonbonded and unbound, and inner-sphere called bonded and bound. Zipse has recently reviewed electronic-structure calculation work in this area [25], emphasizing that calculated transition-state structures often indicate significant interaction between the ET partners. However, the calculations do not directly address the size of H_{ab} , and are mostly on “stripped down” models that often do not very closely reflect the structures of compounds studied experimentally, and the distances calculated are for gas-phase structures lying on exceptionally “soft” energy surfaces, so their applicability to reactions in solution is not clear at this point.

Both the Ebersson and Kochi groups base their practical identification of reactions as inner-sphere upon comparison of observed rate constants for intermolecular ET reactions with calculated ones for outer-sphere reactions in their sense, that is, small H_{ab} reactions so the barrier does not depend upon H_{ab} , using some version of ET theory. When an observed reaction is significantly faster than predicted by the two-state model but with $\Delta G^* = \lambda/4$, it is deemed to have inner-sphere character, that is, to have an H_{ab} that is >1 kcal/mol, so the barrier is significantly affected. How large an effect the use of $H_{ab} = 1$ kcal/mol has depends strongly upon the vertical reorganization energy λ . For the classical two-state Marcus–Hush model, $\Delta G^* = \lambda/4 - H_{ab} + (H_{ab})^2/\lambda$, so an H_{ab} of 1 kcal/mol corresponds to 10 % lowering of the barrier from $\lambda/4$ at $\lambda = 40$ kcal/mol, 19 % lowering at $\lambda = 20$, and 38 % lowering at $\lambda = 10$ kcal/mol. Unfortunately, there is no way of experimentally dissecting H_{ab} from the other parameters that determine the rate constant for intermolecular interactions. Kochi’s group has particularly emphasized another factor than large H_{ab} (but which is not independent of the size of H_{ab}) that leads to larger than “expected” rate constants. Intermolecular ET reactions require an encounter complex formation constant (K_e , unit M^{-1}) to make the units come out right. The expressions usually used for estimating K_e implicitly assume that there is no driving force for association [21c], but this is often not the case. Kochi’s group has emphasized that large association constants do occur for good donors with good acceptors, such as alkylated aromatics with NO^+ , and amines with CBr_4 , and calls them “quasi-covalent bonded” [26]. Ebersson’s interpretation of an electron-transfer mechanism in the nitration of easily oxidized aromatics has been modified with this idea [27]. Because there is experimentally no way of separating the effect of a large K_e from that of a large H_{ab} in causing k_{ET} for intermolecular reactions to increase, and steric hindrance lowers both, these factors appear to be lumped together in discussions of Ebersson–Kochi inner-sphere reactions. Most recently, Kochi’s group has focused on the big difference between rates of charge separation upon quenching of quinone excited-state acceptors by alkylated aromatic donors, where unhindered donors (such as hexamethylbenzene) show much faster quenching, especially in less polar solvents, and are designated inner-sphere, relative to hindered donors (such as hexaethylbenzene) where steric interactions lower K_{eq} and H_{ab} [28]. Hubic and Kochi

especially emphasize that the Rehm–Weller equation was derived assuming only diffusional encounters, that is, small K_e values so that encounter complex decay as well as its formation is diffusion-controlled. They see, however, excited-state emission that requires the extended lifetime that accompanies high K_e values, but these systems still follow the Rehm–Weller equation [28b]. The estimation of H_{ab} for any intermolecular reaction from the observed rate constant seems to invite considerable speculation. Values for five other ET parameters (K_e , ΔG° [29], λ_s , λ_v , and $\tilde{\nu}_v$), none of which can typically be accurately measured independently, are required. Indeed, it appears likely that at least some intermolecular reactions may usually proceed through a variety of transition states, which presumably have a spectrum of values for H_{ab} [21], as indicated from self-electron-transfer rate-constant measurements on phenyl-substituted N,N' -bis(bicyclic) hydrazine radical cations [30].

In contrast to the experimentally based work discussed above, in the most recent comprehensive theoretical discussion [21d], Bixon and Jortner state that the question of whether non-adiabatic or adiabatic algorithms describe electron-transfer reactions was settled in the 1960s, and that the majority of outer-sphere electron-transfer reactions are non-adiabatic. This is certainly true for the reactions that occur in the Marcus inverted region in which these authors are interested, but we think the question of whether reactions in the normal region are best treated by adiabatic theory that includes an electronic transmission coefficient or by non-adiabatic equations remains to be established.

10.3 Bond Cleavage

10.3.1 Reductive Cleavage of Single Bonds

Addition of an electron to a molecule populates an antibonding orbital; this can greatly weaken bonds, even being dissociative (breaking them without thermal activation) if the orbital populated is sufficiently localized. Reductions sometimes lead to low activation energies for breaking C–C bonds even when the populated orbital is highly delocalized, as for **1**[•] [7]. The most synthetically important electron-transfer reaction is probably the production of organometallic RM from alkyl halides, RX, by reaction with metals, most recently discussed in detail by Riecke and coworkers in the context of comparing reactions of organic halides with activated zinc to those with many other reductants [31]. These reductions are argued to involve single-electron-transfer processes, from the (usual) loss of stereochemistry at the carbon being reduced, the tertiary > secondary > primary alkyl halide rate preference, and the reactivity of aryl and vinyl as well as alkyl halides. Electron addition to alkyl chlorides, bromides, and iodides (RX) is dissociative, the free energy of R^\bullet and X^- decreasing as distance increases, as discussed by Savéant and coworkers [32], who considered adiabatic theory for such reactions at electrodes [33]. The intrinsic barrier for dissociative cleavages includes, besides the solvent and inner reorganization energies, the bond-dissociation energy for the breaking bond.

Dissociative reduction reactions of the C–X bonds of alkyl halides [34], certain benzyl halides [35], α -haloacetophenones [36], C–S bonds in sulfonium salts [37], and O–O bonds in peroxides [38] were studied with the use of electrodes as well as electrochemically generated aromatic radical anions as reductants. Such reductions can be complicated by electrode material effects, reduction of the radical product in a wave not resolved from that of the starting material, and double layer effects. Maran and coworkers discuss estimating the standard potential for such irreversible electrochemical reactions [38b]. Savéant's group notes that different profiles for cyclic voltammetry peak width versus scan rate are observed for $\text{Me}_2\text{S}^+\text{CH}_2\text{Ph}$ at 293 K (broader at high and low scan rate) and 273 K (increasing width as scan rate is increased), and relates this difference to the cleavage being concerted at 293 K, but a short-lived intermediate being present at 273 K. They also discuss the theory for dissociative electron transfer that takes into account that the fragments are initially formed in a solvent cage, causing large entropy contributions [39]. Arene radical anions are intermediates in the electrochemical reduction of fluoromethylated arenes, which has been studied in detail with the use of both electrochemistry and redox catalysis [40]. In contrast to other ArCX_3 molecules, which proceed through carbenes generated by CX bond cleavage in ArCX_2^- intermediates, the $\text{X} = \text{F}$ dihalobenzyl anions protonate and reduce a second CF bond faster than they lose fluoride. The nature of Ar and solvent are both important in determining the relative rates of accepting electrons, bond cleavages, and diffusion to the electrode.

A principal mechanistic question for alkyl halide reductions has been the degree of bonding of the metal to the halide at the transition state, that is, whether the reaction is inner-sphere in the Taube sense (see Scheme 1). The M_s symbol refers to solid metal, and less is known about reactions that occur at solid surfaces than those in solution because of problems with studying kinetics (unless the surface is an electrode). Rieke and coworkers emphasize quantities that can be measured, the $\ln(k_{\text{RX}}/k_{n\text{-RX}})$ for secondary ($s\text{-RX}$) and tertiary ($t\text{-RX}$) halides relative to primary ones ($n\text{-RX}$), which they summarize for 14 reactions [31]. The $\text{Co}^{\text{II}}/\text{RI}$, $\text{Cr}^{\text{II}}/\text{RBr}$, and $\text{Cr}^{\text{II}}/\text{RCl}$ cases are completely established as Taube inner-sphere reactions [10]. They show the largest selectivity, $\ln(k_{t\text{-RX}}/k_{n\text{-RX}})$ and $\ln(k_{s\text{-RX}}/k_{n\text{-RX}})$ values of over three and one, respectively. At the other extreme, reaction of RBr with magnesium is extremely unselective [41], and is now usually accepted to be outer-sphere,

Scheme 1. Reductive cleavage of organobromides by a divalent metal M.

Scheme 2. Kimura and Takamuku's S_N2 , ET competition.

although stereochemical results have led to considerable speculation about whether the radical intermediates are significantly complexed to the metal surface [42]. Reaction of RBr at an inert electrode shows a spread of <0.5 for these selectivities and Ph_2CO^- , RBr shows $\ln(k_{t-RX}/k_{n-RX})$ of about one and $\ln(k_{s-RX})/k_{n-RX})$ of about zero [43]. Both are often proposed to be Taube outer-sphere, although it has also been argued that the latter might be inner-sphere, through an $[Ar_2CO \cdots Li \cdots BrR]^\ddagger$ transition state [44]. The selectivity of the activated zinc, alkyl bromide reaction most closely resembles the inner-sphere ones [31].

We now turn to the question of how “bound” the transition state for ET in alkyl halide reductions might be [24]. Zipse [25] highlights the experimental work of Kimura and Takamuku on the competition between intramolecular S_N2 at oxygen and ET in the radical anions of aroyl-haloalkanes **4** (see Scheme 2) [45], as well as theoretical studies on simplified systems [46]. For short chains ($n = 1$) only ET product **6** is observed, but when $n = 2$ or 3, mostly S_N2 reaction, producing **5** is observed when $X = Cl$. The rate of disappearance of **4** correlates well with the reduction potential of the parent ketones and solvent polarity irrespective of the ratio between substitution and electron-transfer processes, suggesting a common mechanism for these processes. In a computational study, three transition states for reaction of $MeCl$ with $H_2C=O^{\cdot-}$ have been found, an *O*-alkylation “bound-”, a *C*-alkylation “bound-”, and an ET “unbound” transition state [47]. Shaik has found that ET/ S_N2 pathway calculations are sensitive to both the coordinate system chosen and the choice of wave function; this indicates that the potential energy surfaces are very flat and will be difficult to evaluate properly [48]. The actual branching ratio in these calculations will depend on dynamics as well as energetics, and solvation effects are probably large.

An initially puzzling switch between S_N2 and single-electron transfer chemistry occurs for reduction of dimethyldioxirane with hydrazines **7** and **8** (see Scheme 3) [49]. As expected, a nucleophilic nitrogen of **7** cleaves the $O-O$ bond and acetone is lost, producing hydrazine oxide **7-O** (which is unstable at room temperature, undergoing retro-Diels–Alder reaction). The surprise is that when one more methylene is added to the hydrazine, **8** undergoes a completely different reaction, in which a $C-CH_3$ bond of dimethyldioxirane is broken, producing **8⁺-Me**. This rather clearly involves single-electron-transfer chemistry, the O,O bond-cleaved dioxirane radical

Scheme 3. $\text{S}_{\text{N}}2$ and one-electron reduction of dimethyldioxirane by hydrazines.

anion undergoing facile β -scission to produce acetate and a methyl radical. Ethyl transfer is favored over methyl transfer when methyl, ethyldioxirane is reduced, ruling out significant $\text{S}_{\text{N}}2$ character for the C–C bond cleavage. The methyl radical, however, cannot be generated free in solution because formation of **8⁺-Me** is rather efficient, and free methyl radicals in acetone produce methane rather rapidly. The dioxirane radical anion presumably is formed on the proper face of the hydrazine, suggesting similar transition states in this respect for the $\text{S}_{\text{N}}2$ reduction of **7** and the single-electron-transfer of **8**. The difference in oxidation potential between **7** and **8** is large enough to rationalize the switch in reaction pathways between them [49].

In contrast to the behavior of most alkyl halides, aryl halide reductions produce discrete $\text{ArX}^{\cdot-}$ intermediates, although lifetimes for cleavage of $\text{ArX}^{\cdot-}$ to aryl radicals and halides are rather short [32]. As shown in Scheme 4, heterolytic cleavage of C–X bonds of radical anions R–X, where R can stabilize a negative charge, such as the 2-nitropropyl systems studied by Russell, the *p*-nitrocumyl systems studied by Kornblum, and the aromatic systems studied by Bunnett (the $\text{S}_{\text{RN}}1$ reaction) can lead to radical chain-substitution reactions, which are synthetically valuable [50]. The entering nucleophile Y^- cannot lead to a more easily reduced R–Y product than R–X, or the ET step will fail to carry the chain. $\text{ArX}^{\cdot-}$ cleavages are also chain-carrying steps in certain radical chain dehalogenation reactions [51]. Lifetimes for $\text{ArX}^{\cdot-}$ cleavage have been measured electrochemically [52] and by pulse radiolysis [53]. The spin-bearing aromatic π system is orthogonal to the C–X σ^* bond that becomes populated to allow cleavage, making it appear that out-of-plane

Scheme 4. $S_{\text{RN}}1$ reactions.

deformation of the C–X bond will accompany the cleavage. Polyfluorinated radical anions are of particular interest in this regard because they show exceptionally large fluorine ESR splittings that are incompatible with planar π -aromatic structures [54], and are now interpreted with the aid of semi-empirical calculations as non-planar “pseudo- π ” structures that contain an admixture of σ^* orbitals [55]. Although addition of electron-withdrawing substituents usually decreases $\text{ArX}^{\bullet-}$ cleavage rates (the ground state is stabilized more than the C–X bond cleavage transition state), addition of fluorine substituents causes the opposite effect for CF cleavage. The much more easily reduced pentafluorobenzoate radical anion undergoes CF bond cleavage 2.4×10^3 times faster than the *para*-, 8.0×10^4 times faster than the *ortho*-, and more than 4×10^5 times faster than the *meta*-monofluorobenzoates [55b]. Increased σ -character in the ground state as fluorines are added is argued to be responsible, and methods for making predictions from calculations on these species (for which quite different cleavage behavior is calculated in the gas phase than is observed in solution) have been recently discussed [55b].

The cleavage of strained ring C–C bonds β,γ to the carbonyl group in ketyls (ketone radical anions) was studied quantitatively. The groups of Tanko [56] and Tanner [57] demonstrated that, in contrast to the case for neutral radicals, where it is used extensively, the cyclopropylcarbinyl, homoallyl ring opening of cyclopropyl ketone ketyls is not a good probe for detecting ketyls in a reaction sequence. Even when opening occurs, the equilibrium constant for opening is poor, in contrast to the uncharged case, so ring-closed products are isolated even when ketyls that open were intermediates. Tanko's group showed that spirocyclopropylcyclohexa-2,5-dienone **16** (cleavage rate constant 10^7 s^{-1} , and exoenergetic) does serve as a probe for detecting a ketone radical anion [58a–c]. In contrast to cyclopropylketone ketyls, which cleave much more slowly than their uncharged radical analogues (O^-

16

replaced by H), methylcyclobutylketone ketyl has a rate constant for cleavage that is probably larger than its uncharged radical analog [58d].

10.3.2 Heterolytic versus Homolytic Bond-Cleavage Reactions

A rather subtle point concerning bond cleavages of radical ions was discussed by Guthrie and coworkers [59] emphasizing C–O bond cleavage, and later by Maslak and coworkers [60], using C–S bond cleavage. We shall consider Maslak's experiment here (see Scheme 5). The presence of the nitro group assures which component of the molecule bears the negative charge in the starting materials, **9** and **10**. Reaction A is called a heterolytic cleavage because the electron pair in the cleaving CS bond ends up on the initially neutral group, while reaction B is called a homolytic cleavage because the charge ends up on the initially charged unit, so one electron of the CS bond goes to each unit. The activation energies for cleavage of **9** and **10** are

Scheme 5. Heterolytic and homolytic C–S bond-cleavage reactions.

almost the same, but cleavage B is almost 8 kcal/mol less endoergic, so its intrinsic barrier must be significantly higher than that for cleavage A. The distribution of charge at the transition state is more delocalized for the heterolytic cleavage, A, (both the O_2NAr group and the SAr group stabilize negative charge), than for the homolytic cleavage B, where the $\text{O}_2\text{NC}_6\text{H}_4\text{S}$ group bears most of the charge both in the starting material and at the transition state. It is pointed out that most known bond cleavages of radical ions are of the heterolytic mode, as are the reverse of these cleavage reactions, the synthetically important radical anion coupling reactions that occur in $\text{S}_{\text{RN}}1$ reactions [50].

Heterolytic cleavage of a neutral radical would give a radical cation. β -Halo and other leaving-group-substituted radicals rearrange, switching the position of the leaving group and radical. These reactions were once always written as concerted reactions, proceeding through bridged transition states [61], probably because radical cations were felt to be too unstable to be intermediates. Gilbert, Norman, and Williams had already established by 1980, through identification by ESR of the radical decomposition products as a function of pH, that heterolytic cleavage to radical cations (see Scheme 6) was occurring in α -donating-group-stabilized, β -hydroxy examples of **11**, although the radical cations **12** themselves were too unstable to build up enough for detection [62]. Most recent interest in such reactions has focused on the C–O cleavage of the 3-phosphatyl substituent from 4-radicals in DNA, which gives radical cation **15** and strand cleavage, suggested as the key intermediate in the radiolytic cleavage of DNA by Schulte–Fröhlinde and coworkers [63]. Zipse has suggested, on the basis of calculations, that $\text{S}_{\text{RN}}2$ reactions, in which the radical cation intermediate is avoided by nucleophilic attack on the initial radical, are more likely than cleavage to radical cations [64]. It is not, however, clear that the great favoring of non-ionic over ionic pathways in the gas phase is completely compensated for by the current methods of trying to account for solvation. In any event, Giese's group has assembled an impressive set of data supporting the intermediacy of **15** in aqueous solution, including the solvent effect on the cleavage

Scheme 6. $\text{C}_\beta\text{--X}$ heterolytic radical cleavage and capture.

rate [65a], observation of photocurrent upon cleavage [65b], ESR observation of the allylic radical after reduction of the allylic cation [65c], how the relative position of various bases in nucleotide oligomers affects the rate of reduction [65d], and Chemically Induced Dynamic Nuclear Polarization (CIDNP) studies on reactions proceeding through chemically generated 4-radicals [65e].

10.4 Rearrangements Initiated by Bond Cleavage in Radical Cations

Removal of an electron from a σ bond formally generates a one-electron σ bond [12], although in real compounds delocalization of the "hole" over several bonds usually occurs. Even if the hole in a radical cation is principally delocalized over a π system, as in $\mathbf{1}^+$, cleavage of a σ -bond can occur rapidly [7]. Cleavage of bonds in rings does not allow separation of the radical and ionic components formed, and can lead either to rearrangement reactions when the odd electron can be disposed of rapidly enough, or to addition of external reagents to the bond that was cleaved. Rearrangement reactions of radical cations will be considered in this section. Gassman and Hershberger found that electrochemically generated triarylamine radical cations catalyze the ring-opening isomerization of quadricyclanes to norbornadienes by an electron-transfer route. Interest here was in using this reaction to turn the exothermic isomerization on and off at will. Less fouling of the electrode was observed when the $\text{Ar}_3\text{N}^{+\bullet}$ -quadricyclane ET was endothermic, and a catalytic turnover of nearly 250 was observed for the parent compound [66].

Roth has especially emphasized the changes in bonding that occur upon electron loss, using CIDNP studies on recovered starting material and products from samples undergoing photo-electron transfer, usually initiated by photolysis of chloranil, as the principal method for deducing cation radical structure [67]. He pointed out that maxima on the neutral surface rather frequently become minima on the radical cation surface. He calls radical cations that have especially large bond-length changes relative to neutral species "nonvertical" ones. This is not the usual meaning of the term, which is that a vertical cation is one with no relaxation at all from the neutral geometry. All cations observed on the timescale of NMR are nonvertical in this sense, because both internal geometry and solvent will have relaxed during the measurement. Extensive skeletal rearrangements occur upon loss of an electron in the absence of nucleophiles from many unsaturated and strained molecules, such as those observed by Roth and coworkers for bicyclo[6.1.0]triene **17**, which gives the allylic CC bond-shift product **18**, the ring-contraction product **19**, and the more substantial rearrangement to the barbaralane derivative **20** (see Scheme 7) [68]. Energy surfaces for photochemical as well as thermal rearrangements of hydrocarbon radical ions are being studied [69]. Several isomers of dihydropentalene radical cations such as **21** have been characterized [70], including the bridgehead dihydro compound **22**, where the subtle question of whether charge is localized or delocalized has been approached through study of its ESR and optical spectra, and computationally [71]. Particularly Bally and coworkers are doing extremely detailed

Scheme 7. Skeletal rearrangements of a bicyclo[6.1.0]nonatriene.

mapping of energy surfaces like that of C_4H_6^+ isomers, containing species such a cyclobutene radical cation, **23**, bicyclobutane radical cation, **24**, and *s*-cis- and *s*-trans-butadiene radical cation [72]; for this, they used a combination of density-functional and other calculations and optical spectroscopy on matrix-isolated species. Of special interest are their comments on calculating the structure of cyclopropylcarbinyl radical cation **25**, which lies in an exceptionally flat potential region.

Brouwer and Wilbrandt have applied resonance Raman spectroscopy and calculations to questions of structure of amine radical cations [73]. Well-resolved Raman spectra of trialkylamine radical cations that are so short-lived that their electrochemical oxidation waves are irreversible may be obtained at room temperature in solution by photoionization and time-resolved detection. Comparison of the observed spectrum with calculations for various isomers provides a powerful method of answering structural questions. Density-functional calculations prove much easier to apply to open-shell species than Hartree–Fock calculations, which require cumbersome and expensive corrections to introduce sufficient electron correlation to consider questions like the charge distribution of disubstituted piperazine (1,4-diazacyclohexane) radical cations. The dimethyl- and diphenyl-substituted piperazine radical cations are delocalized, but charge is localized on one ArN unit of the dianisyl-substituted compound [73d].

In the absence of nucleophiles, the anti- and syn-5-methyl-bicyclo[2.1.0]heptanes **26** and **28** rearrange to the isomeric methylcyclopentenenes **27** and **29** as major products under photo-ET conditions, although some crossover is detected for **28** (see Scheme 8) [74]. Matrix ESR studies show that bridging-bond stretched intermediate cations are formed, and that substituent shift from the middle carbon to form the

Scheme 8. Nonplanar bicyclo[2.1.0]-pentene radical cation.

cyclopentene radical cations occurs overwhelmingly from the endo-directed substituent (see **30**) which is far better aligned with the p-rich orbitals than is the exo-directed substituent. If the bridging CC bond cleaves, the ring flattens out and the stereochemistry is lost because the exo and endo substituents on the bridging carbon become scrambled. The more strained endo-methyl intermediate cation obtained from **28** undergoes such scrambling competitively with substituent migration. The same products are formed from the related 7-methylated 2,3-diazabicycloheptenes, but with these precursors the un-rearranged cations **30** were not detected. Bridgehead-substituted analogs were also studied [74c].

Dinnocenzo and Schmittl showed that *cis*-arylvinylcyclopropane **31** isomerizes to the *trans* isomer upon one-electron oxidation with a huge rate acceleration over that of the neutral compound (ca. 10^{24}). Both *cis* and *trans* radical cations may be detected by ESR, and the isomerization is catalytic in oxidant, because the *trans* radical cation oxidizes the *cis* neutral compound [75]. The open radical cation through which **31**⁺ and its analogs must pass to isomerize also closes to cyclopentene radical cations when substituents on the vinyl group allow significant presence of the proper conformation for closure [76]. CIDNP studies by Roth show that related cyclopropane isomerizations under photo-ET conditions proceed through the neutral triplet diradical produced by back-ET to the initially produced radical cation [77], emphasizing the importance of radical ion lifetime considerations for their reactions.

31

As most recently discussed by Zipse [78], 1,2-shifts and HX eliminations of β -acetoxy and β -phosphatoxyl radicals have often been formulated as proceeding through CO bond heterolysis to give alkene radical cations and delocalized acetoxy or phosphatoxy anions that bond in a second step. Calculations suggest that reactions through the radical cations are not the lowest-energy pathways (in the gas phase, for the stripped-down cases calculated, see also the discussion of Ref. [25] in Section 10.2).

10.5 Additions to Single Bonds of Radical Cations

A particularly well-studied example of an addition reaction proceeding through a radical cation involves the 1-cyanonaphthalene-initiated photocleavage of arylcyclopropanes in methanol, producing methyl ethers by addition of a hydrogen atom to the arylated carbon, and a methoxy group to the adjacent carbon. The reaction was proposed, by its discoverers, Rao and Hixson [79], to proceed through nucleophilic bond opening of the arylcyclopropane radical cation. Extensive studies, by Dinnocenzo and coworkers, involving independent generation of the arylcyclopropyl intermediates and the determination of the stereochemistry of ring opening are consistent with this mechanism, shown for conversion of **32** to **35** in Scheme 9 [80]. The reaction proceeds with extremely high inversion at the carbon attacked by methanol, and with selective cleavage of the most-substituted cyclopropane bond. Tertiary aminocyclopropanes like **36** are cleaved to ketones **37** under photo-ET

Scheme 9. Cyclopropane radical cation cleavage by methanol.

Scheme 10. Cleavage of aminocyclopropanes to ketones.

conditions (see Scheme 10) [81]. The hydrogen atom introduced at the CR^2 carbon is postulated to arise from internal hydrogen atom abstraction as in **38**.

Bicyclobutanes are also cleaved, but small changes in conditions cause different bonds to break, as shown for Moore's bridged bicyclobutane **39** and its derivative **44** in Scheme 11. Thus water, alcohols, and HCN in chloroform or THF add stereospecifically across the bridging bicyclobutane bond to form **40** [82], implying that

Scheme 11. Isomeric cleavages of bicyclobutanes.

Scheme 12. Isomeric methylenecyclopropane radical cations.

the cation attacked is **41**, which is also consistent with CIDNP studies of recovered starting material [83], but in acetone- d_6 , norcar-2-ene **42** is formed, consistent with the side-bond-weakened cation **43** undergoing a 1,3-hydrogen shift. The alkylated derivative **44** produces the bicyclo[3.2.0]hept-6-ene **45**, also consistent with a side-bond-weakened cation, **46**, this time undergoing C–C bond shift [84].

Diarylmethylenecyclopropanes can give two distinct kinds of radical cations, formally 1e- σ -bonded ones from loss of an electron from a CC σ -bond, and alkene radical cations from loss of an electron from the π bond (see Scheme 12). The cation from the saturated carbon diaryl species **47** was shown by deuterium rearrangement to open and reclose, to exchange the vinyl and saturated CH_2 groups upon photo-ET, and to add oxygen to give both the saturated carbon-substituted and alkene carbon-substituted dioxolanes (**48** and **49** respectively) in the presence of oxygen. The ring-opened bisected cation **50** was proposed as the radical cation intermediate [85]. More recently, CIDNP evidence provided further support for the bisected radical cation, and spectroscopic and photoacoustic calorimetry evidence supports back-ET prior to reformation of the three-membered ring [85c]. CIDNP and chemical studies showed that **47** adds to chloranil to give [3 + 2] adducts with the C=O bond of both the saturated-carbon- and alkene-carbon-substituted types in the absence of oxygen, with polarization patterns consistent with the alkene radical cation **50** as the intermediate. In contrast, the isomeric vinyl-carbon diaryl com-

pound **51** does not rearrange to **47** or add to chloranil, and produces a polarization pattern consistent with the cyclopropane-containing olefin cation $\mathbf{51}^+$ as the intermediate. In contrast to formation of both regioisomers of adducts from three-membered ring-cleaved radical cations of **47**, different regioisomers are produced from the thioketal-stabilized radical cation derived from **52**, upon addition to electron-poor and electron-rich double bonds. The photoadduct with tetracyanoethylene is the ketene dithioketal regioisomer **53** (in 85 % yield), but with 9,10-dicyanoanthracene sensitization, addition to furan produces the saturated thioketal regioisomer **54** [85d]. Isomeric epoxide radical cations are also formed. Depending on the alkyl substituents present, three-membered ring-cleaved (2-oxaallyl) or uncleaved oxygen-centered epoxide radical cations are generated [86].

Blackstock employed the significant triplet stabilization of an alkylated trimethylenemethane diradical to probe the photo-ET chemistry of the radical cation (see Scheme 13) [87]. Irradiation into the charge-transfer band of the azo $\mathbf{55}^+$ -TCNE complex is argued to produce the singlet radical ion pair $\mathbf{55}^+$ TCNE $^-$, which must lose nitrogen rapidly to give the singlet trimethylenemethane radical cation-TCNE $^-$ pair $^1[\mathbf{56}^+$ TCNE $^-]$. Back-ET in this pair should be slow because of the spin problem, so unless rapid cage recombination to the unprecedented cyano group adduct **59** occurs, cage escape followed by spin-allowed back-ET to $^3[\mathbf{56}^0$ TCNE] occurs, followed by coupling to the adducts **57** and **58** in the ratio known to occur from $^3\mathbf{56}^0$. In contrast to most photo-ET reactions, different products arise from $\mathbf{56}^+$ and

Scheme 13. Reactions of a substituted trimethylenemethane radical cation.

Scheme 14. Complex cyclopropane ring-opening products.

56⁰; this allows information on ion pairing and back-ET reactions to be more fully considered than usual.

Roth and coworkers' careful studies of the 1,4-dicyanobenzene and phenanthrene-sensitized photo-ET reaction of optically active (+)-sabinene (**60**) in acetonitrile/methanol points out the problem with trying to use cyclopropane cleavage reactions on more complicated systems than those used for mechanistic studies (Scheme 14) [88]. Three-quarters of the product isolated is derived from allylic radical **61**, which is formed with impressive regioselectivity for attack at the most hindered end of the most substituted cyclopropyl bond, with stereochemistry demonstrating that only inversion at the carbon attacked is observed, so methanol capture is faster than ring opening. One-quarter of the product arises from allyl radical **62**, presumably formed by regio- and stereoselective hydrogen atom shift in **60**⁺. Despite these impressive regio- and stereoselectivities, various unselective reactions of the allyl radicals, principally with the dicyanobenzene ET sensitizer, produce a plethora of products, and the major product was only formed in 26 % yield, in the presence of seven other identified compounds [88]. In the absence of methanol to trap the radical cation, the hydrogen-shift isomer **63** was formed in low yield (25 % at 40 % conversion), along with acetonitrile adducts and dimeric material. In contrast to the high stereospecificity when radical cation lifetime is limited by rapid nucleophile trapping, **63** is formed with under 30 % optical purity, indicating that racemization through the open form of intermediate(s) intervenes under these conditions [88b]. Somewhat similar results, with many products formed rather stereoselectively, are observed for reactions of norbornadiene, quadricyclane, and their 7-methylene derivatives [89]. Similar photolyses of geraniol also produce several products, including those of five-membered ring carbon-carbon bond formation and bicyclic ether formation. The product distribution, including stereochemistry, is quite dependent upon photosensitizer, and it is postulated that 1,4-dicyanobenzene provides sufficient driving force to produce solvent-separated

radical ion pairs, but 9,10-dicyanoanthracene is only capable of forming contact radical ion pairs [90a]. ET-photolysis of (+)-*cis*-chrysanthemol produces an oxacylohex-3-ene, formed by intramolecular attack of the hydroxyl group upon the dimethylated terminal position of the double bond, with significant retention of stereochemistry [90b].

Organosilane radical cations undergo alcohol-assisted nucleophilic Si–C cleavage that is rapid enough to compete with return ET to the sensitizer in polar solvents, and that raises quantum yield in nonpolar solvents when a nucleophile is tethered in proper position for the nucleophilic cleavage [91]. Photo-ET allows cleavage of a trimethylsilylated enol ether in the presence of a trimethylsilylated saturated alcohol, although other products are also formed, so the deprotection is not as clean as desired [92].

10.6 Additions to π Systems of Radical Cations

π -Radical anions generated by any means tend to capture electrophiles, and π -radical cations tend to capture nucleophiles. Addition reactions to radical ions generated by photoinduced electron transfer were reviewed by Mizuno and Otsuji [93], and photochemical cycloadditions, including radical-ion ones, by Müller and Mattay [94]. Arnold reported the use of methoxynaphthalenes as photosensitizers (S) for addition of alcohols to 1,1-diphenylethylene, a reaction presumably proceeding by electron transfer to form $S^{\bullet+}$ and $\text{Ph}_2\text{CCH}_2^{\bullet-}$, followed by protonation of the anion and back electron transfer, generating Ph_2MeC^+ , which captures the alcohol [95]. A lack of space and our interests have caused us to focus on reactions of radical cations here. Parker has reviewed the extensive work on the addition of nucleophiles to the π -radical cations from anthracenes and their 9,10-heteroatomic analogs [96]. Gassman and coworkers have especially studied photoelectron-transfer-induced closure of γ,δ -unsaturated carboxylic acids to γ -lactones, such as **64** to **65**, with cyanoaromatic compounds as sensitizers (see Scheme 15) [97]. Yields of **65** are significantly improved when steric hindrance is introduced into 1,4-dicyanobenzene sensitizers by alkylation of the other four positions of the ring, although formation of the unsaturated product **66** remains detectable.

Schmittl has both reviewed [98] and done extensive work on enol radical cations [99]. Ketones appear to oxidize both electrochemically and with many chemical

Scheme 15. Gassman's γ -lactone formation.

oxidants through the lower oxidation potential enol form. However, even when ionizing radiation directly oxidizes the keto form, rearrangement to produce the enol radical cation can be observed in cryogenic matrices, demonstrating that there is little barrier to the isomerization [100]. Dimesityl ketones exist exclusively in their enol form **67**, allowing less mechanistic ambiguity for their reactions. Their cations are stable enough to be detected, and can be prepared by several oxidation methods, from the enol or its derivatives, and cyclize to benzofurans **68** [99]. Electrolytic oxidation of enolates allows their addition to donor-substituted olefins [101], forming carbon-carbon bonds. Chemical oxidants such as manganese triacetate are more commonly used synthetically. A preparation of 4-hydroxyindole (**74**) that features electrolytic oxidation for the key carbon-carbon bond-forming step is shown in Scheme 16 [102]. Both compounds of the mixture **71** + **72** from the electrolytic oxidation step are converted to **73** without separation. The chemistry of electrolytically generated enol ester radical cations was especially developed by Shono and co-workers [103], who obtained α -substituted ketones as products.

Carbon-carbon bond-forming reactions form the core of synthetic organic chemistry, and cycloaddition reactions in which alkene π systems form two CC

Scheme 16. Electrolytic oxidation-based preparation of 4-hydroxyindole.

Scheme 17. Ledwith's radical cation (2 + 2) reaction.

bonds by adding to π radical cations have tantalized organic chemists since the late 1960s. Ledwith and coworkers showed that the strong donor-substituted alkene, *N*-vinylcarbazole (**75**) undergoes chain (2 + 2) dimerization to the disubstituted cyclobutane **76**, catalyzed either by metal oxidants or by photosensitization (see Scheme 17) [104]. They also postulated the currently accepted mechanism (Scheme 17), with an intermediate distonic radical cation **77** having only one of the new carbon-carbon bonds of the product.

Bauld and coworkers, especially, developed the analogous Diels-Alder (4 + 2) cycloaddition reactions. These reactions are conveniently catalyzed by tris(4-bromophenyl)aminium hexachloroantimonate (**78**) or by photosensitization with aromatic nitriles. The radical cation-catalyzed Diels-Alder reaction is far faster than the uncatalyzed one, and leads to some selectivity for attack at the least substituted double bond for the monoene component (Scheme 18, **79** \rightarrow **80**), but only modest *endo* selectivity (*e*- and *x*-**80**) [105]. Cross reactions with two dienes proved to be notably less sensitive to inhibition by steric hindrance of alkyl groups substituted on the double bonds than the uncatalyzed reactions, as cyclohexadiene adds detectably even to the trisubstituted double bond of 2-methylhexadiene (**82**), producing both **83** and **84**. Dienes such as **85** react with donor-substituted olefins (**86**) to principally give the vinylcyclobutene products **87**, but they may be thermally rearranged to the cyclohexene product **88** in good yield [105]. Schmittel and coworkers have studied the cation radical catalyzed Diels-Alder addition of both

Scheme 18. Bauld's radical cation (4 + 2) and (2 + 2) reactions.

allenes and ketenes to pentamethylcyclopentadiene [106]. An interesting oxygenation of arylmethylketenes to diaryldimethylsuccinic anhydrides occurs upon treatment with triarylamine radical cations, although it was concluded that the reaction does not involve ketene radical cations [106b].

Roth and coworkers obtained CIDNP evidence for a singly bonded intermediate in the radical cation Diels–Alder dimerization of spiro[2,4]heptadiene [107]. Gassman and Singleton pointed out that acid-catalyzed (4 + 2) addition reactions can compete with the radical cation chain process when a hindered base (2,6-di-*tert*-butylpyridine) is not included. For 2,4-dimethyl-1,3-pentadiene (**89** of Scheme 19)

Scheme 19. Gassman's proton/radical cation dichotomy.

Scheme 20. Wilson's propenyldimethoxybenzene oligomerizations.

the acid-catalyzed product of addition to the trisubstituted double bond **90** was obtained with acid alone or with **78** in the absence of base, while the product of addition to the disubstituted double bond, **91**, was produced by photo-ET or from **78**/added base [108]. Wilson and coworkers found complex chemistry for **92** upon treatment with **78** in methylene chloride (see Scheme 20) [109]. Although an 86 % yield of the aromatized Diels–Alder adduct **93**, which is also the product formed upon treatment with acid, was obtained in the absence of added base, addition of sodium carbonate, which presumably switches the product mixture towards the radical-cation-initiated reaction, cut the yield of **93** to 26 %, and nine other products were formed in ≥ 1 % yield. Careful work demonstrated that the isomeric dimeric naphthalenes **94** were formed in 1 and 8 % yield, while seven regio- and stereoisomers of the trimeric products **95** were isolated in yields of 3 to 19 % (total yield of identified products, 93 %). Similar products, in slightly different ratios, were formed, starting with the cyclobutane photodimer of **92**. The number of products that form, as well as the change in types of products that form from radical cations upon change of the substitution on donor-substituted olefins make these reactions unsuitable for synthetic use.

As was noted in Scheme 12, distonic radical cations obtained from cyclopropane bond cleavages add oxygen rapidly, producing products with two CO bonds. So do some alkene radical cations. Addition of O_2 to an alkene radical cation is formally a nucleophilic attack by the single alkene π electron on O_2 , and oxidizes both carbon atoms (an alkene radical cations has formally two $\frac{1}{2}+$ carbons, and the adduct a $1+$ and an oxygen-bound carbon). The oxygenation of the radical cation of biadamantylidene (**96**) leads to dioxetanes such as **98** in chain reactions (see Scheme 21) [110]. The reactions may be initiated electrochemically or photochemically, but tris(*o,p*-dibromophenyl)amine hexafluoroantimonate, **97**, is a superior catalyst for the dark reaction of certain tetraalkylalkenes, with turnovers up to ca. 800 at

Scheme 21. Cation radical catalyzed chain oxygenation of olefins.

-78°C . The tribromo analog of **97**, **78**, is not an efficient catalyst because its oxidation potential is not high enough. High turnover is important, because **97** reacts with oxygenated compounds, including **98** and diethyl ether. These reactions are characterized by unusually shaped “E,C, backwards E” cyclic voltammetry curves because the dioxetane radical cation **101**⁺ formed from the starting alkene **99** oxidizes the electrode at a potential at which the electrode oxidizes **99**. Olefin radical cations attack oxygen to form C–O-bonded β -peroxyl radical cations (**100**⁺ of Scheme 21), as shown by isomerization about the central single bond of suitably substituted olefins. The equilibrium is poor up to the formation of **101**⁺, and the reaction only occurs efficiently because reduction of **101**⁺ by the starting alkene **99** is quite exothermic. Low temperature greatly increases catalyst turnover because of the reversibility, **101**⁺ \rightarrow **99**⁺ + O₂. These reactions make **102** and **103** available: neither can be made by ¹O₂ addition, which gives only ene products with alkenes that have abstractable α -hydrogens, or by any other published method. The olefin-face sensitivity for the chain reaction is greater for halogen substitution on the biadamantylidene ring than for the ¹O₂ reaction that produces the same dioxetanes [111]. However, the reaction of Scheme 21 is quite sensitive to alkene structure. It fails for alkenes that do not have at least two α -branched carbons, apparently be-

Scheme 22. Formation of a 4,5-dihydro-1,2,3-oxadiazole-3-oxide.

cause the radical cations react with themselves too rapidly, and also fails for several tetra- α -branched ones such as **104** and **105**, possibly because the $\mathbf{100}^+$ intermediates in these cases do not close rapidly enough [110].

Syn-sesquinorbornene **106** fails to produce the dioxetane with either $^1\text{O}_2$, as well as after several attempts at radical cation oxygenation chain reactions, but reaction with NOPF_6 gave **107**, a derivative of a previously unreported heterocyclic ring system (see Scheme 22) [112]. No **107** was detected upon reaction of **106** with NO , and $\mathbf{106}^+$ is presumably involved in its formation.

The similar radical cation chain oxygenation of dienes to endoperoxides was discovered by Barton and coworkers, who formulated it as a Lewis acid catalyzed reaction that avoided the spin-state problem for triplet oxygen reacting with singlet starting materials to give singlet products [113]. Like the reaction of alkenes, diene-radical-cation-catalyzed oxygenation is a $^1\text{O}_2$ mimic reaction, but has a significantly different substitution pattern for substrates that are successful. The radical-cation oxygenation reactions being discussed produce radical cations that are much better oxidants than the starting compound, producing a characteristic cyclic voltammogram wave shape. However, the unhindered diene **108** has such a short radical cation lifetime, that it does not give this wave shape, although **108** produces **109** with about 260 turnovers at -78°C (see Scheme 23) [110]. The cyclic voltammogram of **110** is not noticeably affected by oxygen, and no oxygenated products were observed. The equilibrium for addition is presumably poor, with closure to form a dioxetane intermediate too slow to compete with CO bond cleavage because the cation is allylic, so Scheme 23 chemistry does not occur. An *s*-cis diene conformation is required for endoperoxide formation, and the *s*-cis form of **110** probably is too high in energy to be populated. However, **111** has enough *s*-cis diene to allow efficient formation of its endoperoxide, **112**. This material cannot be made from **111** with $^1\text{O}_2$; at least six products were formed, but only traces of **112** [110].

Scheme 23. Cation radical catalyzed chain oxygenation of dienes.

Cope rearrangements (3,3-sigmatropic shifts) catalyzed by oxidants are well known, but matrix studies and calculations suggest that the cyclohexanediyl cation **114**⁺ is usually so much more stable than the opened cations **113**⁺ and **115**⁺ that back electron transfer must occur before the CC bond cleavages that generate neutral **113** and **115** will occur (see Scheme 24) [114]. The cation from 1,5-diyne **116** is an exception, because its closed form is much less stable than its bis(allene) Cope rearrangement product **117**⁺, which was independently generated both by oxidation of neutral **117** and by photolysis of dimethylenecyclobutene radical cation, **118**⁺.

Scheme 24. Radical cation Cope rearrangements.

10.7 Trisubstituted Nitrogen Oxidations and Aminium Radical Cation Deprotonations

Because stable products are usually diamagnetic compounds, most reaction sequences proceeding through radical ions involve multistep sequences, and unraveling the characteristics of individual steps can be difficult. Quantitatively studying individual steps has rarely been attempted in most of the product-oriented studies described in Sections 10.3–10.5. As an instructive example of the consideration of individual steps for complex reactions, the timing of electron and hydrogen loss in oxidative amine dealkylation is a long-standing problem that has been considered with various oxidants for decades [115]. Although $R_2NCHR'_2$ is converted to $R_2N^+=CR'_2$ in the steps of interest, hydrolysis usually occurs to generate the dealkylated amine before products are isolated. The question was whether there was initial hydrogen-atom abstraction to produce $R_2NR'_2C^\bullet$, or a one-electron transfer to produce $R_2NCHR'_2\bullet^{+}$ that deprotonates to the same species. Different reagents can obviously give different results, and it would seem to be a reasonably straightforward question to answer, because the products from the oxidant (which are frequently complex) do not have to be considered. More recently, it has been fashionable to study similar questions using more complex systems that are intended to model biological systems. For example, Miwa and coworkers applied hydrogen isotope effects at the methyl group being attacked in oxidative dealkylation of methylated anilines by cytochrome P-450 [116]. They pointed out that the mechanisms should differ in the size of these isotope effects. From literature data on aniline oxidations by other reagents, it was decided that a radical cation deprotonation mechanism, an e^- , H^+ transfer (a), has a small isotope effect ($k_H/k_D \leq 4$), while an H^\bullet transfer mechanism (b), shows a big one ($k_H/k_D \geq 7$). Although it was not obvious what k_H/k_D ought to be for a third mechanism, (c) e^- , H^\bullet transfer, the small isotope effect for P-450 oxidation of *N,N*-dimethylaniline was concluded to show that mechanism (a) occurs [116]. However, later experiments demonstrate that these k_H/k_D ranges are not correct, and that the real ranges are more variable than thought. Dinnocenzo and coworkers showed that k_H/k_D is 6–9 if bases related to quinuclidine are used for deprotonation of the stable tertiary amine radical cation, dianisylmethylamine [117]. Parker and Tilsit found k_H/k_D values for $ArNMe_2$ that varied between 5 and 22 [118], and Mariano and coworkers obtained k_H/k_D values of 5–6 for photochemically generated trialkylamine radical cations by enone anion radicals [119]. Dinnocenzo and coworkers emphasized that the k_H/k_D pattern for a series of substrates with a reagent should be more reliable than the examination of only one, and that the H^\bullet transfer mechanism (b) for *tert*-butoxy radical attack on deuterated $ArN(Me)_2$ has a k_H/k_D pattern that is indistinguishable from that of P-450 attack on these compounds, and that both are significantly different from the e^- , H^+ profile (a) [120]. However, in the most recent studies on both the horseradish peroxidase compounds I ($O=Fe^{IV}por^{+}$) and II ($O=Fe^{IV}por^0$), and $O=Fe^{IV}TMP^{+}$ as a model for cytochrome P-450, both kinetic isotope effects were investigated by looking at the disappearance of oxidant and product isotope effects, to reach a rather different conclusion [121]. There is no kinetic isotope effect for the horse-

radish peroxidase compounds, consistent with the accepted e^-/H^+ -transfer mechanism (a), and it is suggested that $O=Fe^{IV}TMP^{*+}$ also involves (a), but that for this system, H-atom transfer from $ArNMe_2^{*+}$ to $O=Fe^{IV}TMP^0$ competes with back-ET, leading to the observed product isotope effects [121]. Thus, the mechanistic scheme previously considered was not extensive enough, as it ignored back-ET, which completely altered the conclusion reached from the isotope-effect data.

There has also been considerable interest in rate constants for aminium radical cation deprotonations. Dinnocenzo and Banach showed that the maximum rate constant for deprotonation of dianisylmethylamine radical cation occurs for amines whose pK_a for their protonated forms is 8 pK_a units below its pK_a of ca. 18 [117]. Savéant and coworkers have particularly studied 9-substituted *N*-alkylacridans **119**^{•+} [122], which are not only model compounds for NADH, but are especially revealing, because their deprotonated forms **119** oxidize to stable **120**⁺. This allows k_H to be measured by a combination of electrochemistry, redox catalysis, and laser flash spectroscopy, and also the thermodynamics for C–H bond cleavage (expressed as the bond dissociation free energy, BDFE) to be determined through the use of thermodynamic cycles. Marcus-like theory is used to rationalize the fact that the intrinsic barrier for deprotonation, ΔG_0^\ddagger , is little larger than $BDFE/4$, because the solvent reorganization is rather small for compounds of this size. Steric effects are important enough that ΔG_0^\ddagger becomes noticeably greater than $BDFE/4$ as the size of the R^2 group in **119** increases. It is pointed out that the $\Delta G_0^\ddagger \approx BDFE/4$ relation also fits previous work on deprotonation of alkylaromatic and dianisylmethylamine radical cations [112].

The inner-sphere character (in all three senses, see Section 10.2) for electron removal from R_2N groups will be considered next. The change in pyramidalization at nitrogen upon electron loss causes relatively large λ_{in} values for compounds containing R_2N groups [123]. Unpublished work by Trieber, Nelsen, and Kentamäa on oxidation of diaminosulfides such as **121** addresses the Taube and Ebersson/Kochi definitions of inner-sphere in R_2N oxidations. Trieber showed that oxidation of **121** electrochemically or with triarylamine **78**⁺ gives **121**^{•+}, but oxidation with NO^+ , despite the electron transfer being 11 kcal/mol exothermic, does not. As indicated in Scheme 25, the *N*-nitrosamine **123** and protonated amine **125** are isolated instead; we suggest by the S–N⁺ heterolysis of **122**. Because NO^+ is a small, powerful electrophile, it is not surprising that **121** would react with it through the S_N2 lone-pair attack shown, instead of single-electron transfer. Amines that are difficult to oxidize and even alkenes react with NO^+ by two-electron attack. NO^+ reacts with most

Scheme 25. NO^+ oxidation of a diaminodisulfide in solution.

substrates with which it undergoes exothermic single-electron transfer, by producing the single-electron-transfer products, but **121** does not, presumably because **122** undergoes more rapid $\text{S}-\text{N}^+$ heterolysis than N^+-NO homolysis. There is no proof that **122** is not formed by the SET coupling route shown. In this regard, however, the reaction of **121** with NO^+ in the gas phase (studied by Kentamäa) is particularly interesting, because only $\text{121}^{\cdot+}$ is formed, with no **123** or other cleavage product observed. This strongly suggests that **122** is not formed in the gas phase. It should be noted that this gas-phase reaction will proceed through an ion-dipole complex that is bound much more tightly than the solution reaction encounter complex would be, because solvation greatly decreases the 10–20 kcal/mol encounter complex binding energies that are typically found in the gas phase. Although Ebersson and Kochi call systems in which H_{ab} is greater than 1 kcal/mol “bonded” [22, 23], and Kochi emphasizes “bonding” in systems with large K_e values in solution [26], structures of the much stronger encounter complexes formed in the gas phase between hydrazines and their radical cations are calculated not to be intermediate between the geometries of the neutral and cation, but to clearly have neutral and

radical cation components whose geometry is only changed as expected to allow as close an approach as possible [130e]. The switch in products between gas phase and solution suggests that single-electron transfer is more rapid than S_N2 attack of the diaminosulfide nitrogen in the gas phase, which appears to be opposite to the case in solution. A principal difference between the solution- and gas-phase reactions is the obvious lack of solvation in the gas phase, and hence of λ_s , which would favor the single-electron-transfer reaction that is observed.

10.8 Studies Focusing on Electron Transfer Kinetics of Organic Systems

Savéant's electrochemical work on reductive CX bond cleavage is highlighted in Section 10.3, and Chapter 9 (Volume I, Part 1) discusses other heterogeneous electron-transfer experiments. Only homogeneous reactions will be discussed here.

10.8.1 Intermolecular Reactions

The forty-year-old Marcus cross-rate theory for calculating the rate constant for electron-transfer reactions between different species (k_{ij} of Eq. 1) was derived classically and ignores separation of λ_v and λ_s , tunneling, and variations in both the preexponential factor and K_e [21].

Most studies have been on metal coordination compounds [21, 124], where work terms are typically required to account for multiply charged species approaching each other, leading to additional parameters being required. For reactions with 0/+1 charges as shown in Eq. 1, Marcus's equations simplify to Eq. 2.

$$k_{ij}(\text{calcd}) = (k_{ii}k_{jj}K_{ij}f_{ij})^{1/2} \quad (2a)$$

$$\ln(f_{ij}) = [\ln(k_{ij})]^2 / [4 \ln(k_{ii}k_{jj}/Z^2)] \quad (2b)$$

K_{ij} and k_{ij} are the equilibrium constant and cross reaction rate constant for Eq. 2, k_{ii} and k_{jj} are the self-exchange ET rate constants, and Z is a preexponential factor usually set at 10^{11} (results are quite insensitive to its value). Because K_{ij} can be calculated from the difference in formal oxidation potentials for the components, Eq. 2 states that k_{ij} only depends upon the formal oxidation potential and intrinsic ($\Delta G^\circ = 0$, or self-ET) rate constant k_{ii} for each couple involved.

There is no transient to follow for the $\Delta G^\circ = 0$ self-ET reaction (see Eq. 3),

Scheme 26. Self-exchange rate constants (25 °C in acetonitrile).

so obtaining k_{ii} values for reactions that are too fast to follow on a laboratory time scale rely on magnetic-resonance line broadening, developed at about the same time as Marcus cross-rate theory. The first organic radical cation ever isolated, that from tetramethyl-*p*-phenylenediamine (**126**, Scheme 26), was used by Weissman in developing the slow-exchange region NMR line-broadening technique for determining k_{ii} , published in the same year as McConnell's similar work on organocopper compounds [125]. The slow-exchange-region NMR method is especially simple, because only the radical cation concentration needs to be known for accurate k_{ii} values to be obtained [125]. However, k_{ii} for **126**^{0/+} is too large to keep the measurements in the desired region in acetonitrile, and acid added to stabilize **126**⁺ in water resulted in the wrong k_{ii} being reported initially (protonated **126** does not electron-exchange, and hardly any neutral **126** is present at pH 5, but the equation used to calculate the rate constant assumes pseudo-first-order conditions) [126]. Grampp and Jaenicke studied *p*-phenylenediamine derivative self-ET using ESR line broadening, which is more appropriate for their large k_{ii} values ($1.5 \times 10^9 s^{-1}$ for **126**^{0/+} exchange at 25 °C in acetonitrile) [127]. Nelsen's group established that tetraalkylhydrazines have exceptionally large and substituent-dependent geometry changes upon electron loss [123], and that many examples with bis(bicyclic) substituents, such as **127**–**129**, were isolable as radical cations and give measurable slow-exchange NMR k_{ii} values, all a factor of $\geq 8 \times 10^4$ smaller than that for **126** [128]. The near-180° lone-pair–lone-pair twist angle present for *N,N*-bis(bicyclic) hydrazines like **127** and near-0° twist angle present for *N,N'*-bis(bicyclic) hydrazines like **128** and **129** (twisted 13° in crystals) greatly restrict the geometry change between neutral and cation (the cations have 3e- π bonds, and twist angles near 0/180°) [128] relative to the 90°-twist-angle acyclic hydrazines. This results in a much larger λ_v and smaller k_{ii} for **130**^{0/+}, whose k_{ii} value is a factor of 4.5×10^6 smaller than **128**^{0/+}, and 5×10^{11} smaller than **126**^{0/+} [129]. The bond-length-change, force-constant algorithm [21] used for calculating λ_v of metal-centered species is not very appropriate for nitrogen-centered organic species, where changes in bond angles and twist angles are very important. The λ_v values can be much more easily calculated without going through expressions containing force constants, from the total energies for the geometry-optimized reduced and oxidized states, and their vertical ET partners [128a].

Experimental determination of k_{ij} usually employs stopped-flow measurements, which require stability of both the diamagnetic and paramagnetic oxidation states

on the timescale of the experiment. Most studies have focused on metal-centered examples, and commented upon good agreement between Eq. 2 and experiment [21b,c]. Pladziewicz and Nelsen have studied a wide range of structural types of 0/+1 organic and substituted ferrocene cross-ET reactions [129c, 130]. Their reaction set presently includes 141 reactions between 45 compounds (91 reactions of 27 compounds in the most recent publication [130c]). The $k_{ij}(\text{calcd})$ values using E^o values measured by cyclic voltammetry and best-fit $k_{ii}(\text{fit})$ values for each couple are almost all within a factor of 0.5 to 2 of k_{obs} ; the average difference in activation barrier, $|\Delta G^{\ddagger}_{ij}|$ is 0.18 kcal/mol. Equation 2 unquestionably correlates the data successfully for a large variety of structural types. The $k_{ii}(\text{fit})$ values are systematically slightly smaller than k_{ii} values measured under self-exchange conditions, possibly because H_{ab} is more favorable for self-exchanges [129c]. The dynamic range of $k_{ii}(\text{fit})$ values is very large, 2.3×10^{14} , shown for selected compounds as relative $\Delta G^{\ddagger}_{ii}(\text{fit})$ values in Scheme 27. By pitting large and small barrier compounds against each other, $k_{ii}(\text{fit})$ values can be obtained for low barrier compounds that cannot be measured directly under self-exchange conditions (such as **131** and **132**). Grampp and Jaenicke studied **132**^{0/+} under self-exchange conditions, and showed that the

Scheme 27. Intrinsic barriers from cross-rate studies.

rate constant obtained, even after correction for diffusion, is not that to which simple Marcus theory refers, because solvent tumbling becomes the rate-limiting step [127c]. Combining very fast and very slow compounds also allows rate constants to be measured for high barrier compounds that cannot be studied under self-exchange conditions because the reactions are too slow to show even NMR line broadening, and/or the radical cations are too unstable to survive until equilibration of electron transfers occur (such as **137** and **138**). The barrier of aromatic compounds **131–133** cover a 3 kcal/mol range, and their barriers correlate well with AM1 calculations of the enthalpy portion of λ_v . Ferrocene and three methylated derivatives including decamethylferrocene **134** have $k_{ii}(\text{fit})$ values within experimental error of each other, a significantly smaller range than for k_{ii} values measured by fast-exchange NMR line broadening [131]. The $k_{ii}(\text{fit})$ value for the *p*-phenylene diamine derivative substituted with bulky alkyl groups (**135**) is within experimental error of that for the tetramethyl compound (**126**) which is not consistent with the aryl- π -system touching transition states favored by Grampp and Jaenicke for self-ET of **126** (and nearly universally assumed to represent the transition states for intermolecular ET between aromatic systems) [126]. Tetratolylhydrazine **136** has a $\Delta G^\ddagger_{ii}(\text{fit})$ value comparable to other aromatic amines, much smaller than hydrazines with alkyl substituents. Rate differences caused by differences in steric hindrance are obvious for the 2-atom π -system tetraalkylhydrazines. Larger H_{ab} for tetramethylhydrazine (**138**) than for the tetrapropyl (**137**) and tetraisopropyl (**130**) derivatives presumably is responsible for faster ET for reactions involving **138**. Even changing from methyl to ethyl substituents decreases $k_{ii}(\text{fit})$ by a factor of 2000, and in computer modeling, prevents significant direct NN π system overlap. The dynamic range in $k_{ii}(\text{fit})$ values for hydrazines is a notably large 10^{12} , indicating how important λ_v effects can be for organic compounds. The applicability of Eq. 2 to reactions involving compounds having a large range of k_{ii} indicates that the thermodynamics and intrinsic barrier indicated by the formal potential and $k_{ii}(\text{fit})$ values for each couple are in fact all that are needed to predict intermolecular electron-transfer rate constants to a surprising degree of accuracy. Because many of the reactions are non-adiabatic (Eq. 2 was derived using classical adiabatic theory), and especially because the ET parameters $\tilde{\nu}_v$ and λ_v vary very widely, this behavior is surprising. For Eq. 2 to work so well, the averaging of preexponential factors for the self-reactions must be as good an approximation as averaging of the intrinsic barriers.

10.8.2 Intramolecular Reactions: Donor–Bridge–Acceptor Systems

ET systems consisting of an electron donor and acceptor linked by a bridge (**D–B–A** systems) have controlled geometry if the bridge is rigid enough, making it likely that there actually is a single-electron-transfer transition state, and electron transfer within them is first order, so guessing the K_e that is necessary for intermolecular systems is not necessary. Completely arbitrarily, we shall not discuss the large amount of work done on aromatic-bridged and directly bonded **D–A** systems, which will be covered in a future volume of this series. Miller, Closs, and coworkers studied ET rate constants in systems including the 5 α -androstane-3,16-diyl acceptor–

**139 (10 σ)**

biphenyl systems shown as **139** [132]. Electrons were indiscriminately added (or removed) from the acceptor and biphenyl groups by pulse radiolysis, and the rate at which the radical ion approaches its equilibrium distribution between acceptor and biphenyl units was determined by optical absorption measurements. Even with the tiny H_{ab} arising from the small electronic overlap through the 10 σ -bond shortest pathway between the units, k_{ET} proved too large to measure ($k_{ET} > 2 \times 10^9 \text{ s}^{-1}$) for the fastest system, where the acceptor is hexahydronaphthoquinon-2-yl, which has $-\Delta G^\circ \cong \lambda$. Smaller k_{ET} was observed when $-\Delta G^\circ$ exceeded λ , and this system was the first for which the long-sought “Marcus inverted region,” where making an ET reaction more exoergic makes it slower, was observed [132]. The widely quoted H_{ab} of 6.2 cm^{-1} for **139** was obtained assuming a constant H_{ab} for all examples and analysis of the rate constant using Jortner’s single averaged frequency rate expression [21d] with $\tilde{\nu}_v$ fixed at 1500 cm^{-1} for all examples (how quantitative each assumption is might be considered, because the structural changes in the acceptors used are large enough to change ΔG° for ET from biphenyl radical anion to acceptor by over 2 eV, and might be expected to cause some variation in both H_{ab} and $\tilde{\nu}_v$), and somewhat arbitrarily fixing λ_v at 0.45 eV. It was later noted that λ_v is substantially larger than 0.45 eV for biphenyl $^{\cdot-}$, but that the biphenyl rotation component has such a low frequency that it can be lumped with λ_s , so the results are presumably not affected [133]. Related systems with cyclohexane and decalin bridges as well as linked cubane bridges have also been studied, and the dependence of H_{ab} on number of bonds (n) discussed [134]. These compounds follow the predicted $e^{-\beta n}$ relationship that arises from the proportionality of H_{ab} to n and the proportionality of rate constant to $(H_{ab})^2$ for these non-adiabatic ET reactions.

Paddon-Row and coworkers studied a revealing series of rigidly double σ -bond linked systems, where **D** = 1,4-dimethoxynaphthalene-2,3-diyl, **A** = 7-dicyanomethylene (**140**, even numbers of σ -bonds in the shortest pathway) or **A** = bis-electron-withdrawing-substituted cyclobutene (**141**, odd number of σ bonds), see Scheme 28. Photoexcitation gives the charge-separated form $^+\text{D}-\text{B}-\text{A}^-$, leading to very large dipole moments: 26 Debye for **140(4)**, 37 for **140(6)**, 55 for **140(8)**, 68 for **140(10)** [135]. Pulse radiolysis studies gave k_{ET} that was too fast to measure for all of **140(4)** to **140(12)**, but the CT bands observed gave estimates of H_{ab} of 1300, 480, and 240 cm^{-1} for **140(4)** $^{\cdot-}$, **140(6)** $^{\cdot-}$, and **140(8)** $^{\cdot-}$ respectively [136]. Fluorescence quenching allows the study of charge separation in the series **140(8)**–**140(12)**, and both emission and absorption CT bands were studied for **140(4)**. A Hush-type two-state analysis of the radiative decay rate constants gave the H_{ab} values shown in Scheme 28, which are 28 to 17 % of those quoted above for the radical anions [137a]. Charge recombination was studied with time-resolved

Scheme 28. Paddon-Row type rigidly linked D-B-A molecules.

microwave conductivity in dioxane and less polar solvents. In contrast to charge separation, k_{BET} is very dependent upon solvent polarity, and local donor excited states are populated, producing delayed donor fluorescence [138a]. Bixon, Jortner, and Verhoeven have re-analyzed the data for radiative emission from these and related compounds in terms of a three-state model, instead of the two-state model previously used [137c, 139]. The two-state model only includes the ground state, S_0 (DBA) and the first excited state, S_1 (D^+BA^-), lying ΔE above S_0 , but the next, locally excited state S_n (DBA)* lying ΔE^* above S_1 also needs to be included for these systems. It was concluded from the solvent dependence of the emission from the charge-transfer state that the three-state model is necessary, and data were re-analyzed using it, giving the result that the H_{ab} values previously extracted both from absorption and emission spectra actually refer principally to S_0 - S_n mixing, and not the S_0 - S_1 mixing to which they were attributed, so that H_{ab} for S_0 - S_1 mixing in these compounds is at least an order of magnitude smaller than previously believed.

Zimmt and coworkers have studied **D** = dimethoxyanthracene analogs of **140** and **141**, such as **142(7)** and the stereoisomeric, single cis bicyclic ring fusion compounds like **143(9)** [140]. The latter compounds have “C-clamp” shapes that place **D** and **A** fairly close but far enough apart so that solvent can get between them, and have much longer distance through-bond than through-space/solvent pathways for

ET. Fluorescence quenching studies establish that, in contrast to the all trans-fused **142(n)**, the C-clamp **143(n)** molecules show faster ET in more polar solvents, and exacting analysis in terms of modern ET theory establishes that polar solvents raise H_{ab} . Similar conclusions have been reached by Paddon-Row and coworkers for similarly-shaped species [141].

Many larger systems, having three to five charge-bearing centers of various sorts have been studied, often ones with other **D** and **A** units, including many porphyrin and quinone systems intended to mimic biological systems. This work will be covered in the subsequent volumes of this monograph.

If the bridge is flexible, various orientations of donor and acceptor are obviously possible. Verhoeven and coworkers have established a “harpooning” mechanism in which electron-transfer charge separation precedes bridge conformational change for formation of D^+, A^- exciplexes in the absence of solvent by using 4-cyanonaphthyl-*N*-arylpiperidines **144**, which have the aryl groups far apart in the ground state conformation, but can move them close together by flipping the piperidine ring to a boat conformation **145** [142]. In gas phase, jet-cooled molecules, where the aryl group is phenyl or tolyl, the threshold excess energy required to attain the emission attributed to the boat-form exciplex **145** is 4.8 kcal/mol, but it is only 2.1 kcal/mol for the compound where the aryl group is anisyl. The barrier required to flip the piperidine ring in ground state **144** is about 10 kcal/mol, but exciplex formation stabilizes the product in the charge-separated form, lowering the barrier.

10.8.3 Intramolecular Reactions: Intervalence Compounds

Among the most revealing electron transfer systems ever devised are “symmetrical,” localized (also called Robin–Day [143] Class II) intervalence compounds, which have identical charge-bearing units (**M**) joined symmetrically by a bridge (**B**), and an overall charge that places different charges on the charge-bearing units, so they may be symbolized as “ $M-B-M^{n+1}$ ” systems. It may be seen that they are special cases of **D–B–A** systems, in which **D** and **A** only differ in charge. Such compounds fix one more ET parameter than do **D–B–A** systems; ΔG° is zero. Furthermore, as Hush pointed out, the charge-transfer band maximum transition energy (E_{op} or $\tilde{\nu}_{max}$) is equal to Marcus’s total reorganization energy λ (when vibronic coupling is ignored), and the transition dipole moment for this band allows simple calculation

of the electronic interaction energy H_{ab} if the electron transfer distance d is known (See Volume I, Part 1, Chapter 8).

The intervalence compound concept was developed for compounds having transition metal coordination complex **M** groups, and such systems have been studied most, but we only consider organic-centered systems here. Cowan and coworkers were the first to apply the term to organic compounds, pointing out that tetrathiafulvalene (**132**, Scheme 27) is a delocalized (Robin–Day Class III) intervalence complex [143b]. So are the other species shown in Scheme 27, including the first organic radical cation ever isolated, **126**^{•+}. From Hush theory, E_{op} for a Class-III compound is equal to $2H_{ab}$, providing a far more accurate measure of H_{ab} than can be achieved for any Class-II compound, where ϵ_{max} and band width at half height must be determined as well as a value assumed for the electron-transfer distance (it cannot be easily measured). The $E_{op} = 2H_{ab}$ relationship becomes increasingly far off as direct overlap of the charge-bearing units occurs, as for hydrazine radical cations [129b]. Hush, Paddon-Row, and coworkers used this relationship to measure H_{ab} in the gas phase for Class-III bis(alkene) cations like those from the all anti-bridged **146(n)** and the less favorably aligned mono-syn-bridged **147(n)** (see Scheme 29) [144]. The separation between the symmetric and antisymmetric π -bond combination orbitals was measured by photoelectron spectroscopy and equated with $2H_{ab}$. Direct overlap makes the splitting different from $2H_{ab}$ for **146(0)**. The relatively low resolution of PE spectroscopy unfortunately makes an experimental number not determinable for **146(3)** and higher oligomers. It is not obvious how large the solvent effect on H_{ab} ought to be; solvation energies for radical cations are very large compared to H_{ab} , and electron distributions and hence solvation energies should be different for the ground- and excited-state radical cations.

For **126**^{•+} in acetonitrile, $H_{ab} = 8150 \text{ cm}^{-1}$, while for the Creutz–Taube complex, **148**, which also has a five-bond, six-membered aromatic-ring pathway between the charge-bearing centers, H_{ab} is ca. 1000 cm^{-1} , emphasizing the better overlap between the charge-bearing units and bridge in organic compounds than in transition metal coordination complexes [145]. The relatively small H_{ab} for **148** makes its

Scheme 29. Gas-phase H_{ab} values from PE spectroscopy.

Hush-type intervalence band occur in the IR region. From the $E_{\text{op}} = 2H_{ab}$ assumption for Class-III intervalence compounds in solution, consistent analyses of Class-II and Class-III compounds for both metal and organic-centered intervalence complexes are obtained in several instances [145].

Pioneering work by Mazur invoked fast-electron transfer on the infrared time scale for the anion radical **149** [146a], although later work using dynamic ESR showed that electron exchange between the keto units, which also requires counterion exchange in the nonpolar solvents in which **149** is stable, is much slower than previously thought [146b]. Considerable work has been done on dimeric perchlorotriarylmethanes connected by a bridge, **150** [147], but most interest has been in the diradical oxidation state of these systems. It has been suggested that the radical anion oxidation states should be classified by whether the diradical oxidation state is a ground-state singlet (feudal) or a triplet (allodial). Arene-bridged bis(quinone) and bis(dicarboxydiimide) radical anions that are both Class II and Class III have been prepared and studied by Miller and coworkers [148]. Optical spectra of diarylamine-centered intervalence radical cations linked *meta* to aromatic systems (minimizing H_{ab} and maximizing stability of high spin ground states for poly(radical-cations)) [149], and ones linked *para* (maximizing H_{ab}) have also been studied [150], as well as a 9-nitrogen one including both types of links [149h].

Saturated-bridged intervalence complexes were designed to use the large vibrational reorganization energies of hydrazines to obtain systems for which optical analysis could be carried out accurately and k_{ET} could also be measured [151]. Although a charge-transfer absorption band can be seen for some $\Delta G \neq 0$ **D-B-A** systems like **140(4)** and **140(6)** of Scheme 28, these systems have great intensity borrowing from a local excitation band, and the H_{ab} obtained from it, although appropriate for calculating the charge separation rate, does not really give the **D-to-A** H_{ab} value of Hush theory [139]. This problem does not arise for the dinitrogen-centered $\Delta G^\circ = 0$ compounds discussed below, which have a larger energy gap between local excitation and charge transfer, as well as a symmetry difference for the transitions. Rather small structural changes in nitrogen-centered charge-bearing

Scheme 30. Saturated-bridged bis(diazonium) and bis(hydrazine) intervalence compounds.

units cause large changes in vertical reorganization energy, as for bis(diazene) radical cation **151** and bis(hydrazine) radical cations **152** and **153**, where the vertical reorganization energy E_{op} approximately doubles upon alkylation of each dinitrogen system. Scheme 30 shows optically derived ET parameters at 25 °C in acetonitrile for each compound. The large increase in E_{op} between **151** and **152** occurs because geometry reorganization and hence λ_v is much larger in bis(hydrazine) radical cations like **152**, where the neutral hydrazine unit is strongly pyramidalized, and even the oxidized hydrazine unit is significantly pyramidalized [151a]. The diamagnetic oxidized dinitrogen unit in the bis(diazene) is planar at nitrogen, and corresponds geometrically to a doubly oxidized hydrazine, which is also planar at nitrogen [127]. It has been shown by magnetic resonance line broadening that intermolecular electron transfer between a hydrazine radical cation and its dication is significantly faster than between the neutral and the hydrazine radical cation, despite the presence of a work term for the $1+/2+$ exchange which slows down the former [128a].

Organic-centered localized intervalence compounds are of interest because they allow the accuracy of calculations of ET rate constants from optically-derived ET parameters in systems that have the maximum number of parameters well defined to be tested. The rate constant for intramolecular exchange between the dinitrogen units of bis(diazonium) and bis(hydrazine) radical cations may be accurately measured by dynamic ESR for the large nitrogen hyperfine splitting when k_{ET} is near 10^8 s^{-1} [151a]. The large λ_v of hydrazines takes the charge-transfer band maximum from the near-IR region, where it lies for transition-metal-centered systems with large λ_s and for 4σ -bond linked bis(diazonium) radical cation **151**, to the UV region, corresponding to a big increase in the ET barrier. However, k_{ET} for **152** was too

small to be measured by ESR, and that for **151** too large [151a]. Getting compounds into the right rate range by tinkering with the alkyl groups and ET distances proved possible. The diisopropyl compound **153** has a 1500 cm^{-1} smaller E_{op} than its methyl-substituted analogue **152**, causing an increase in k_{ET} that allowed its measurement in acetonitrile using the long-range splitting of hydrogens on the bridge anti to the hydrazine unit, and in methylene chloride, the smaller λ_{s} put k_{ET} into the correct range for measurement using the larger nitrogen splitting [151b]. Replacing the alkyl groups by a bicyclic ring in **154** lowered E_{op} by 3200 cm^{-1} without significantly affecting H_{ab} , putting the k_{ET} into the desired region [151c]. Unfortunately, the change of the hydrazine units from trans to cis fused also caused by the structural change of the alkyl groups apparently introduces conformational complexity that causes anomalous temperature sensitivity of the rate constant [151c,d]. Increasing the number of saturated bonds connecting the diazenium units from 4 to 6 in **155** increased E_{op} by 3900 cm^{-1} and cut H_{ab} by a factor of 3, putting its k_{ET} in the desired window for measurement by ESR [152].

Synthesis of bis(hydrazines) with aromatic bridges is much easier than that for the saturated-bridges species because *tert*-butyldiazenium salts may be added to aryl dilithiums. The *p*-phenylene-bridged radical cation **156** (see Scheme 31) is localized [153]. Although the bridge is the same as for **126**, greater delocalization of the charge in the charge-bearing unit is important for lowering H_{ab} enough so that $H_{\text{ab}} < \lambda/2$ (which causes localization); H_{ab} for untwisted **156–158** is estimated at ca. 4600 cm^{-1} from the cosine relationship for H_{ab} at each *N*-bridge connection

Scheme 31. ■■

[153b]. Lambert and Nöll have shown that tetraanisyl-*p*-phenylenediamine, which has a very small λ_v , as do other triarylamines, is a localized (Class II) system, although it has only a tiny ET barrier [150b]. The k_{ET} of **156** is too large to measure very accurately by ESR, but addition of methyl groups to the bridge in **157** and **158** twists the hydrazines into poorer conjugation with the ring, lowering H_{ab} and placing k_{ET} in the measurable range, as are compounds **159–161**, the latter two because of smaller H_{ab} caused by the greater number of bonds between the hydrazine units [134c].

Having both rate and optical data on several compounds of Schemes 30 and 31 allowed more detailed consideration of how to best obtain optical parameters from the charge-transfer bands that accurately describe the energy surface for thermal electron transfer. The optical spectra of **156–158** are significantly broader than Hush's "high-temperature limit" (charge-transfer band width at half-height $\Delta\tilde{\nu}_{1/2}(\text{htl}) = (16RT \ln(2)E_{\text{op}})^{1/2}$, see Chapter 8 of Volume I, Part 1). The reason is apparently not principally the vibronic coupling broadening dependence of $\Delta\tilde{\nu}_v$ suggested by Hush, both because $\Delta\tilde{\nu}_{1/2}$ is quite bridge-dependent with the same hydrazine charge-bearing units (**159–161** have $\Delta\tilde{\nu}_{1/2}$ near the $\Delta\tilde{\nu}_v(\text{htl})$ value in acetonitrile, in contrast to **156–158**, which have broader bands), and because the broadening is quite sensitive to solvent, being larger in methylene chloride than in acetonitrile for all systems studied [151–153]. Vibronic coupling theory does not properly explain the charge-transfer bands of the high λ_v bis(hydrazines), as shown by failure to obtain reasonable partitioning of λ_v from λ_s using it. Rate constants calculated from optical parameters using single $\tilde{\nu}_v$ versions of vibronic coupling theory are far from those observed and have anomalous calculated temperature effects. When Hush's simple two-state treatment is used with diabatic energy surfaces that fit the charge-transfer bands [meaning that the diabatic surfaces are not exactly parabolas, because parabolas give $\Delta\tilde{\nu}_{1/2}(\text{htl})$], quite accurate predictions of the rate constants are obtained using Hush's formula for H_{ab} [154]. An experimental estimate of the electron-transfer distance d gives slightly better fit to the observed data than using the distance between any specific atoms in these molecules. Studies of k_{ET} and the optical spectra of **158**, **160**, and **161** in methylene chloride at various concentrations show that although ion-pairing effects increase E_{op} detectably and the ion-pairing equilibrium constant is a few thousand M^{-1} , calculation of k_{ET} from $\Delta G^\circ = 0$ for extraction of the optically derived parameters does not introduce much error compared to calculating it using the proper ΔG° because of compensating changes in the H_{ab} obtained [153d]. The solvent reorganizational energies for the compounds of Schemes 30 and 31 do not follow dielectric continuum theory predictions that λ_s will depend linearly upon the bulk solvent parameter $\gamma = 1/n^2 - 1/\epsilon_s$ (where n is the refractive index and ϵ_s is the static dielectric constant). The relationship between the optical spectrum of the 2+ oxidation state of **156** and its singlet, triplet splitting is that expected from a three-state model (there are two equal energy excited states because the hydrazine units are the same in the dication), and the H_{ab} values for its 1+ and 2+ oxidation states are quite similar [155].

Although the Marcus–Hush two-state system analysis of the optical spectrum gives accurate rate constants for **156–161**, adding a second benzo ring to give the anthracene-9,10-diyl-bridged compound **162** produces a k_{ET} at least a factor of 100

larger than expected from the two-state model [156]. The optical spectrum is also anomalous, and reveals why this compound is different. A band corresponding to bridge oxidation ($^+\text{Hy-B-Hy} \rightarrow \text{Hy-}^+\text{B-Hy}$) is observed at lower transition energy than the Hush-type ($^+\text{Hy-B-Hy} \rightarrow \text{Hy-B-Hy}^+$)* band, because the aromatic bridge λ_v is so much smaller than the hydrazine one that λ plus ΔG° for bridge oxidation is still smaller than λ for the Hush-type band. This occurs because the bridge oxidation state lies too close in energy to the hydrazine-oxidized ground states of the system. Application of a simple three-state model was found not to produce a $\text{Hy-}^+\text{B-Hy}$ ground-state energy minimum, so the latter is not an intermediate in the ET.

Because ϵ_{max} for the Hush-type charge-transfer band of an intervalence compound is proportional to H_{ab}^2 , ET within intervalence compounds for which the charge-transfer band may be easily seen is at least close to being adiabatic. For adiabatic reactions, H_{ab} affects the ET barrier through the relationship $\Delta G^*[(1 + 0.25C)/(1 + C)]\lambda/4 - H_{ab} + H_{ab}^2/\lambda$ ($C = 0$, using the Marcus-Hush assumption of parabolic diabatic surfaces, and C is the fitting parameter for a quartic term added to the diabatic surfaces) [154]. The preexponential factor for adiabatic reactions does not contain H_{ab} , and is only linearly dependent on $\tilde{\nu}_v$. A $\tilde{\nu}_v$ of 400 cm^{-1} is often used for metal coordination complexes, and is near 1500 cm^{-1} for aromatic compounds. AM1-based dynamics calculations on bis(hydrazines) and bis(diazonium) salts indicated intermediate values of 800 cm^{-1} and 1100 cm^{-1} are more appropriate [151d]. There has been much more interest recently in non-adiabatic electron-transfer reactions [157]. When H_{ab} is small, ΔG^* is only significantly determined by λ , and the preexponential factor is proportional to H_{ab}^2 . Using classical theory, the size of $\tilde{\nu}_v$ does not appear in the rate expression. Elliott and coworkers have studied the $\text{Fe}(\text{bpy})_3$ -centered system **163**, achieving the first

comparison of optical and thermal ET parameters for a non-adiabatic electron transfer [158]. It has k_{ET} small enough to be measured by NMR line broadening because of a small H_{ab} of about 6 cm^{-1} estimated from the optical spectrum. The charge-transfer band had a reported ϵ_{max} of $0.24\text{ M}^{-1}\text{ cm}^{-1}$, extracted by subtraction of spectra for other species in electron-transfer titrations from a region with absorption corresponding to many times this number.

29. It seems universally accepted that ΔG° can be accurately determined by electrochemistry, but this requires the use of model compounds for most intramolecular cases, and can only be true for reactions that are slow enough to allow equilibration of solvent fluctuations. Quantitative electrochemical measurements are usually made in polar solvents like acetonitrile containing 0.1 M of a supporting electrolyte. The “corrections” for solvent changes for reactions run in other solvents are not very accurate, although widely used.

Volume I

Part 2

Methods and Techniques

1 Classical Methods

Andreja Bakac

1.1 Introduction

The methods described in this chapter are used to study solution reactions that take place within a wide range of timescales, from several microseconds to several days or longer. In the present context, the word “classical” is used to describe reactions between chemical species that are either stable and used as such or generated in a chemical reaction in a rapid pre-mixing step which does not use radiation, photochemical or electrochemical sources.

Standard methods and techniques are covered and examples of chemical reactions are provided to illustrate the applicability of a particular method/technique to specific chemical systems and to demonstrate the utility of the information obtained in deciphering the mechanism. It is not the purpose of this chapter to provide an in-depth review of the chemistry involved.

For the most part, the methods described allow direct observation of reactants, products, or intermediates by monitoring the change in some physical property, such as absorbance, electrical conductivity, NMR and so forth. In addition, there is a section on indirect methods and special cases to describe competition reactions and slow exchange reactions, that is, those reactions not amenable to study by NMR or ESR line broadening.

Unless stated otherwise, the rate constants are quoted at 298 K.

1.2 Mixing Methods

1.2.1 Manual Mixing

For reactions requiring more than about a minute for completion, the reactants are mixed manually, and concentration changes are monitored by spectroscopic, elec-

trochemical, or chemical methods [1]. Electron-transfer reactions often are accompanied by optical absorbance changes in the visible and/or UV range, which makes the spectrophotometric monitoring of the reaction progress especially convenient. The actual handling of the solutions, especially if an air-free atmosphere is desired, often involves the use of syringe-septa techniques. The reaction is initiated by injection of the last reagent through the septum, and the absorbance changes are followed either at a single wavelength or by use of a rapid-scan instrument which can collect data over a range of wavelengths in a short time.

The most common type of rapid-scan instruments, diode array, utilizes an array of detectors and reverse optics, that is, the light is dispersed after it passes through the sample. Such instruments can collect a spectrum in a fraction of a second, thus ensuring that the solution composition remains unchanged during the acquisition time, provided the half-time for the reaction is longer than several seconds. In the example shown in Figure 1, the spectra of a decaying Cr^{V} complex [2] were collected by use of a diode array spectrometer over a period of 30 s.

Another type of rapid-scan instrument uses a combination of a spinning grating and single detector.

Over the past two decades, spectrophotometers have become much smaller and lighter owing to the use of compact modern electronics and sturdy, but lightweight housings made of synthetic materials. The instruments are routinely operated by use of computers which also digitize the data and calculate rate constants.

Figure 1. The decay of $[\text{14}]\text{aneN}_4\text{CrO}^{3+}$ as studied by use of a diode array spectrophotometer. The spectra, from top to bottom, were taken 3, 8, 12, 20, and 30 seconds after the initiation of the reaction. (Previously unpublished data from the author's laboratory).

The constant temperature in the cell compartment is maintained with circulating thermostatted water through the cell holder or by use of a specially designed cell holders with thermoelectric temperature control.

Data treatment consists of the fitting of single-wavelength data to appropriate kinetic equations. Global analysis is required for complicated, multistep reactions. Global analysis packages are provided these days almost routinely by instrument manufacturers.

1.2.2 Rapid Mixing

For the reactions reaching completion in less than a minute, the manual mixing of the reagents and the initiation of data acquisition would overlap with the chemical reaction. A number of rapid mixing and relaxation techniques are available to cover these shorter timescales, as described below.

Continuous flow

This method operates under steady-state conditions which makes it possible to measure high reaction rates with slow detection methods. The fast streams of two reactant solutions flow from the loading syringes into the mixing chamber. From there, the reaction solution passes through the observation chamber and is finally disposed into the waste receptacle. The reagents are continuously replenished and the spectroscopic measurements are done at selected points along the observation tube. At a constant flow rate, these points represent different times. Alternatively, the measurements can be done at a fixed point and the time variation achieved by varying the flow rate. Reactions with half-lives of 1 ms or longer can be measured by this technique owing to the availability of efficient mixing chambers [1].

One of the problems with classical continuous-flow instruments is the large volume of reactants needed for each kinetic run (10–100 mL), although this requirement has already been greatly reduced from the early days when several liters of solution was needed [1].

In a modification of the continuous-flow method known as “continuous-flow method with integrating observation (CFMIO)” [3] the mixer is incorporated into the observation tube and the reaction is monitored along the flow path rather than perpendicular to it. In this mode, the observation begins immediately after the reactants enter the mixing/observation tube; this dramatically extends the upper limit of the rate constants than can be measured. Also, the signal is improved by the increased path length.

Kinetic equations have been derived for the calculation of rate constants from measured absorbancies, the flow rate, and known spectral data for reactants and products [4]. For an ideal mixer, the expression for the first-order rate constant is given by Eq. 1,

$$k = \epsilon v/l \quad (1)$$

where v is the flow velocity, l the path length, and ε is defined in Eq. 2.

$$\frac{\text{Abs}_v - \text{Abs}_{\text{inf}}}{\text{Abs}_0 - \text{Abs}_{\text{inf}}} = \frac{1 - e^{-\varepsilon}}{\varepsilon} \quad (2)$$

Here Abs_v is the measured absorbance at a given velocity, and Abs_0 and Abs_{inf} are the absorbances corresponding to the reactants and products, respectively.

For second-order reactions with equal concentrations of the reactants, the corresponding expressions are given in Eqs 3 and 4,

$$k = \varepsilon v[A]_0/l \quad (3)$$

$$\frac{\text{Abs}_v - \text{Abs}_{\text{inf}}}{\text{Abs}_0 - \text{Abs}_{\text{inf}}} = \frac{\ln(1 + \varepsilon)}{\varepsilon} \quad (4)$$

where $[A]_0$ represents the initial concentration of the reagents.

A time resolution of approximately 10 μs is possible with the CFMIO method, although at such short times the mixing and chemical reaction take place simultaneously and the analysis becomes more complicated. Nonetheless, the method was used successfully in a study of the reactions of iron(III) and ruthenium(III) polypyridine complexes with several transition metal cyano compounds [3], but each experiment required approximately 300 mL of solution. The measured rate constants for electron transfer exceeded $3 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$.

The measuring cell which serves as a basis of the CFMIO method [3] can also be used in a stopped-flow mode by positioning of one or more observation channels perpendicular to the flow tube. This combined stopped-flow, continuous-flow method [5] was used to determine the effect of surface-active substances (sodium dodecyl sulfate or dodecyltrimethylammonium chloride) on electron-transfer reactions between metal complexes.

The technique of continuous flow was further improved and expanded with the introduction of pulsed flow, which uses short pulses of constant-velocity flow and cuts the reagent consumption to 3–4 mL per determination [6]. The combination of large flow velocities and short times was experimentally achieved by use of a special syringe ram assembly.

The instrument uses a radial mixer/observation cell shown in Figure 2. The reagents are introduced through alternating slits arranged around the observation tube and then travel through the tube at a rate of 2 m/s to 9 m/s.

This instrument was tested in a study of several electron-transfer reactions, including that between IrCl_6^{2-} and $\text{Fe}(\text{CN})_6^{4-}$ [6], $k = 4.1 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$. The data treatment according to the equations given above for pseudo-first-order conditions showed the calculated pseudo-first-order rate constants to be a function of flow velocity, the more so the higher the concentrations and reaction rates. This deviation from the expected behavior was rationalized by the effects of mixing and an empirical relationship was found between the true rate constant (k), the measured value (k_{obs}) and flow velocity, Eq. 5,

$$k_{\text{obs}} = k - (1/v)(mk/l) \quad (5)$$

Figure 2. Top and end views of a radial mixer/observation cell used in pulse-accelerated-flow spectrometer. W, windows, A and B, reactants. Reproduced with permission from S. A. Jacobs, M. T. Nemeth, G.W. Kramer, T. Y. Ridley, and D. W. Margerum, *Anal. Chem.* 1984, 56, 1058. Copyright 1984 American Chemical Society.

such that the intercept of the k_{obs} vs $1/v$ plot gives k . In the above expression, m is a proportionality constant.

Under second-order conditions, calibration plots were necessary to extract the true rate constants from the observed values of $(\text{Abs}_v - \text{Abs}_{\text{inf}})/\text{Abs}_0 - \text{Abs}_{\text{inf}}$. The rate constants of $1.6 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ for the reduction of $\text{Fe}(\text{phen})_3^{3+}$ by $\text{Fe}(\text{CN})_6^{4-}$ and $(0.11\text{--}2.5) \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ for a series of reactions between $\text{Cu}(\text{dmp})^+$ and copper(III) peptide complexes were obtained [6].

The pulsed-flow method evolved further into the pulsed-accelerated-flow method [7]. Here, the solutions have a range of flow velocities owing to the constant flow

acceleration during each push. Equation 6, where k_m is a mixing proportionality constant, is applicable to both pseudo-first- and second-order conditions.

$$1/k_{\text{obs}} = 1/k + 1/k_{\text{mix}} = 1/k + 1/k_m v \quad (6)$$

Rate constants as high as $1.2 \times 10^5 \text{ s}^{-1}$ and $2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ were measured with a special twin-path cell. Even higher rate constants (up to $5 \times 10^5 \text{ s}^{-1}$) were measured later, but data treatment became more complex, because an additional term, second-order in velocity, was found to contribute to mixing at such high rates [8].

Stopped flow

This is the most widely used of all the rapid-mixing techniques. The pistons of the drive syringes are pushed pneumatically to force the two reactant solutions through the tubing into the mixing chamber, from there into the observation chamber and finally into the stopping syringe, Figure 3. The flow is suddenly arrested as the piston hits a mechanical stop and simultaneously triggers the data-acquisition process. The observation post is perpendicular to the direction of the flow. Standard instruments mix equal volumes of the two reactant solutions, but it is possible to change the mixing ratio by use of syringes of different bore or by varying the travel distance of the two drive syringes [4].

Some of the early stopped-flow work concentrated on the oxidations of iron(II) complexes shown in Eqs. 7–9 [9, 10].

Figure 3. Schematics of a stopped-flow instrument.

The technique turned out to be extremely useful for kinetic determinations and the early home-made instruments were soon replaced by commercial products.

The limit for the measured rate constants is determined by the mixing rate and the instrument's dead time, defined as the time required for the solution to travel from the mixing chamber to the observation point. Nowadays, half-times in the millisecond range can be measured routinely. An extension of accessible rates up to 2000 s^{-1} through algebraic corrections for mixing effects was discussed [11]. Under the assumption that the behavior of the solution at short times after mixing in the stopped-flow is described by the same equations that were found applicable for pulsed-accelerated flow, the precise rate constant can be obtained from a set of experiments carried out under pseudo-first-order conditions by use of Eq. 10.

$$k_{\text{obs}} = k[\text{excess reagent}]/(1 + k[\text{excess reagent}]/k_{\text{mix}}) \quad (10)$$

The fit to this equation will provide values of k and the mixing constant k_{mix} , which is constant for a given instrument. The $\text{IrCl}_6^{2-}/\text{Fe}(\text{CN})_6^{4-}$ reaction was again used as a test case. The value, obtained by use of Eq. 10, was $4.2 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$. The good agreement with other determinations justifies and supports the assumptions made above.

In addition to standard methods of monitoring the reaction progress by UV and visible spectroscopies, other detection methods also can be used. For example, electron-transfer reactions between monomeric and dimeric metal carbonyl complexes in Eq. 11 have been studied by infrared stopped-flow spectroscopy utilizing a tunable CO laser as a source of infrared radiation and a HgCdGe detector [12].

In another study [13], rapid-scan infrared spectra were recorded over the course of the reaction between $\text{Fe}(\text{CO})_3(\text{PPh}_3)_2$ and I_2 in CHCl_3 . At a 1:1 ratio of reactants, the $\text{Fe}(\text{CO})_3(\text{PPh}_3)_2$ signal at 1878 cm^{-1} first disappeared but then slowly reappeared to the extent of 50 %. An intermediate was clearly observed in the spectrum at 2050 cm^{-1} . The data were interpreted by invoking the formation and subsequent disproportionation of a 19-electron iron(I) intermediate.

The stopped-flow mixing can be combined with a variety of detection methods in addition to spectrophotometry. A nice example is provided by a rapid-scanning EPR spectrometer in which the reagents are delivered from a stopped-flow mixer into an EPR cell. This action triggers the generation of a wave form to drive a rapid-scan unit. The rate constants are obtained from the digitized spectra [14].

The oxidation of phenol by ferrate(V) was studied by use of pre-mix (stopped-flow) pulse radiolysis [15]. To avoid complications from the thermal reaction be-

tween Fe^{VI} and phenol, the pulse was applied a short time (100 ms) after the mixing to generate Fe^{V} by reducing Fe^{VI} with hydrated electrons and hydroxyisopropyl radicals. The ensuing reaction between Fe^{V} and phenol, Eq. 12, proceeds in part by formation of an iron(III)-catechol complex and has an overall rate constant of $3.8 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$.

A combination of stopped-flow mixing and laser-flash photolysis of the newly generated species is finding increasing use in studies of biological reactions. In a recent example [16], a ferrocyanochrome $\text{a}_3\text{-CO}$ adduct was produced by the stopped-flow mixing of the fully reduced cytochrome caa_3 and CO. The follow-up photolysis caused rapid dissociation of CO. The recombination of the reduced ferrocyanochrome and CO, and the reaction with O_2 were then observed as kinetic steps.

An important development in stopped-flow spectrophotometry is sequential flow, whereby an intermediate is first generated in a pre-mix stage, and then allowed to react in the next step with the reagent of interest, as shown in Figure 4. Solutions A and B are mixed first, and the resulting mixture is allowed to flow into the aging loop. At this point, the flow is temporarily arrested to allow the reaction to go to completion. When the flow is resumed, the aged solution is mixed with reagent C from the third syringe and the observation begins. In principle, one could build a

Figure 4. Schematics of a sequential stopped-flow instrument.

number of successive stages into such an instrument, and there are known examples of instruments with up to five mixers [17], but two mixers are much more typical. As an example, a detailed kinetic and thermodynamic study of the formation and subsequent homolysis of several short-lived organochromium complexes was made possible by use of three-syringe, two-mixer stopped-flow [18].

In the first stage, the organochromium complexes were generated in a Fenton-type scheme, Eqs. 13–15.

The organochromium ions were then mixed with a solution of a scavenger (X) for $\text{Cr}_{\text{aq}}^{2+}$ and/or $\cdot\text{CR}_2\text{OH}$. The rapid removal of homolysis fragments, Eq. 16, reversed the equilibrium of the reaction of Eq. 15, and led to direct measurement of k_{hom} ($\leq 300 \text{ s}^{-1}$).

1.3 Relaxation Methods

These methods are applicable to chemical reactions at equilibrium. If the equilibrium is suddenly perturbed by a change in temperature, pressure, or some other parameter, then the system will relax toward the new equilibrium position. The rate constants for the forward and reverse steps can be determined from the rate of relaxation [19, 20].

Another important source of perturbation of a chemical system is light, such as a laser flash. The irradiation can cause a rapid photochemical reaction, such as photolysis of a single bond. The reverse, thermal reaction will then regenerate the reactant(s). This method differs from the other relaxation methods mentioned above in that the relaxation process brings the system back to its initial state rather than to a new equilibrium. The amount of energy deposited with a flash is often large enough to temporarily perturb even an irreversible thermal system, which makes this technique applicable to both reversible and irreversible reactions. Flash photolytic methods are a subject of a later chapter and will not be dealt with here.

The data treatment and kinetic equations for relaxation kinetics have been developed and discussed in detail [1, 19–21]. For a set of two opposing first-order reactions, Eq. 17.

the relaxation is a first-order process and the observed rate constant is $k_1 + k_{-1}$, Eq. 18.

$$-dx/dt = (k_1 + k_{-1})x \quad (18)$$

Here x represents the displacement of the concentrations from the new equilibrium, Eq. 19.

$$x = [A] - [A]_{\text{eq}} = [P]_{\text{eq}} - [P] \quad (19)$$

In relaxation kinetics, reaction rates are often expressed in terms of relaxation time, which is the reciprocal of the rate constant, Eq. 20,

$$\tau = (k_1 + k_{-1})^{-1} \quad (20)$$

and represents the time necessary for the concentration to decrease to $1/e$ of its value.

For a system of two opposing first-order reactions one would expect first-order behavior, as experimentally observed. In relaxation kinetics, however, even non-first-order reactions will exhibit first-order kinetics provided the perturbation of the system is small enough so that higher-order terms in x can be neglected. For a system of opposing second- and first-order reactions, Eq. 21,

one can derive the rate law of Eq. 22.

$$-dx/dt = k_1 x^2 + (k_1[A]_{\text{eq}} + k_1[B]_{\text{eq}} + k_{-1})x \quad (22)$$

At small x , the term $k_1 x^2$ becomes negligible, and the relaxation time is given by Eq. 23.

$$\tau^{-1} = k_1([A]_{\text{eq}} + [B]_{\text{eq}}) + k_{-1} \quad (23)$$

In multistep reactions with n reversible steps, there will be n relaxation times, each of which will contain kinetic information on all the steps involved in the reaction.

1.3.1 Temperature Jump

The size of the change in equilibrium constant with temperature is a function of ΔH° , as described by the van't Hoff equation, Eq. 24:

$$d(\ln K)/dT = \Delta H^\circ/RT^2 \quad (24)$$

In practice, a measurable change in concentration can be achieved with a temperature rise of 1–10 °C. As noted above, the concentration changes need to be small to reduce the kinetics to first-order behavior. The standard heat sources are thermostatted baths or electrical, microwave, or optical (laser) heating. The electric heating is often accomplished by a discharge of a capacitor through an electrically conducting solution ("Joule heating") [22–24], which limits the technique to polar solvents containing moderate to high concentrations of salts. Rise times of 1 μ s or less are not uncommon [23].

Temperature jump [25] with Joule heating was used in an early study of rapid outer-sphere electron-transfer reactions [22] between polypyridine metal complexes and hexachloro- and hexabromometalates, Eq. 25,

for which $k_f = 2.3 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ and $k_r = 2.8 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ at 10 °C. The data for this and related reactions were fitted to the Marcus equation for calculation of the reorganization energies ranging from 4 to 7 kcal/mol.

Microwave heating provides reasonable temperature jumps (≥ 1 °C) in 1 μ s, which is somewhat inferior to electrical heating. The method requires a solvent that absorbs in the microwave region of the spectrum. Most polar solvents are acceptable.

Optical heating uses a high-power pulsed laser and produces a reasonable increase in temperature in very short times (ps to μ s range). The reaction solutions must absorb at the wavelength of the laser pulse, usually in the near infrared [26]. Either the solvent or a solute can serve as the light-absorbing material. Clearly, the solute used for this purpose must not interfere with the chemical reaction being studied or with the detection method used. The absorbance of the solution has to be adjusted properly so that the temperature rise is significant, but the temperature gradient—always present when laser heating is used—not too steep. Strongly absorbing solutions cannot be used because the temperature rise is limited to a small segment of the solution at the front end of the cell. A block diagram of a laser-heated temperature-jump instrument is shown in Figure 5.

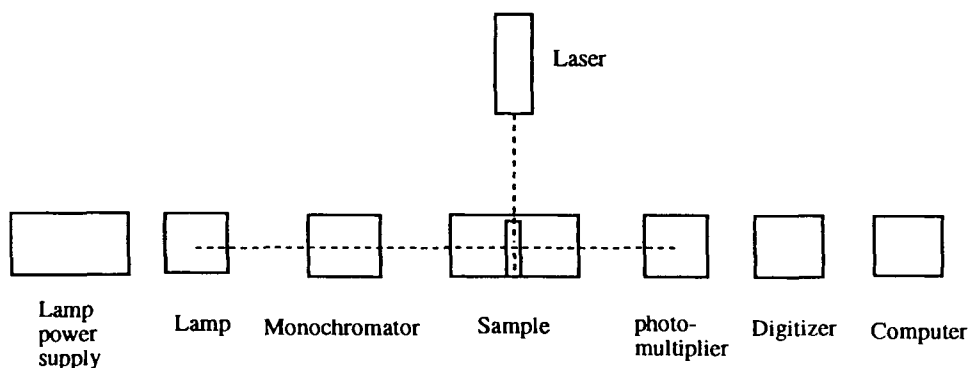

Figure 5. Block diagram of a laser-heated temperature-jump instrument.

In recent years, temperature-jump methods have been used widely in studies of enzymatic and biological electron transfer. These methods seem to be ideally suited for the task owing to the existence of finely balanced, easily perturbed equilibria in biological systems. Kinetic determinations are facilitated by the large molar absorptivities of most metalloenzymes, so that even small concentration changes provide measurable signals.

An example [27] is provided by the recent determination of the rate of intramolecular electron transfer in a copper-containing amine oxidase, $\text{Cu}^{\text{II}}\text{-topa}_{\text{NH}_2}/\text{Cu}^{\text{I}}\text{-topa}_{\text{SQ}}$, Eq. 26, where topa represents 3-(2,4,5-trihydroxyphenyl)-1-alanine.

The observed rate constant, $k_{\text{obs}} = 150 \text{ s}^{-1}$, was combined with an independently determined equilibrium constant (0.7–1) to calculate the forward rate constant $k_f \approx 70 \text{ s}^{-1}$.

To circumvent the equilibrium requirement, which is the greatest limitation of temperature jump, attempts have been made to combine this technique with some others. The stopped-flow temperature jump, for example, has found use in studies of reactions involving the formation of intermediates on not-too-short timescales ($\geq 10 \text{ ms}$) [23]. In this method, the temperature jump is applied during the course of the stopped-flow reaction. The equilibrium between the reactants and intermediates is perturbed, which permits a direct study of the fast steps occurring prior to the rate-determining step [28].

An adaptation of the temperature-jump method, named indirect laser-induced temperature jump [29], was used in studies of distance dependence of electron transfer at electrodes. A pulsed Nd:YAG laser was used to cause a sudden ($< 5 \text{ ns}$) change in temperature ($< 5 \text{ K}$) at an electrode/electrolyte interface. The increase in temperature causes a change in the open-circuit potential. The relaxation step is a function of the dissipation of thermal energy and the rate of electron transfer between the electrode and its redox partners.

The kinetics of electron transfer through ferrocene-terminated alkanethiol monolayers on a gold electrode were determined as a function of the number of methylene groups in the alkyl chain tethering the ferrocene to the electrode [29].

1.3.2 Pressure Jump

At a constant temperature, the dependence of the equilibrium constant on pressure (P) is given by Eq. 27.

$$d(\ln K)/dP = \Delta V^\circ/RT \quad (27)$$

The molar volume change ΔV° is small for most reactions in solution, which requires large pressure changes (≥ 50 atm) for a measurable perturbation of an equilibrium [30]. This technique has not found much use in electron-transfer reactions, but various absorption–desorption phenomena, association–dissociation equilibria, and structural relaxations have been studied successfully. Pressure jump is also quite useful in biological studies of folding and unfolding of proteins and DNA owing to the pressure sensitivity of these processes [31].

1.3.3 Spin-Relaxation Methods

Spectroscopy and kinetics are related through the dimension of time—spectroscopy uses frequency, kinetics uses time. The interaction of the nuclear magnetic moment with an outside magnetic field forms the basis of NMR. In the closely related ESR, it is the electron's magnetic moment that interacts with the magnetic field.

NMR line broadening

Invaluable kinetic information has been obtained by NMR line broadening in exchange reactions [32] that occur on millisecond to submillisecond time scales. Not only is the technique applicable to solvent- and ligand-exchange processes, but also to electron exchange, even though paramagnetic species are involved. The nucleus that is being monitored resides on a ligand and is far removed from the metal center. This distance makes the signal reasonably sharp but shifted. The shift often facilitates the measurement by precluding the overlap between the signals for the two oxidation states. The width of the NMR signals associated with the ligand is a function of the time that the respective nucleus (^1H , ^{13}C , ^{15}N , ^{31}P , etc.) resides at a given site. The longer the residence time (i.e., the slower the electron exchange between the metals), the sharper the signals. As the temperature rises, the rate of exchange increases and the lines broaden and eventually coalesce. Finally, as the exchange rate increases even further, the signal becomes sharp once again. These changes in the appearance of the ^1H NMR spectrum with temperature are illustrated in Figure 6 [33] for an inner-sphere, chloride-bridged electron-exchange reaction (Eq. 28).

The observed signals correspond to the porphyrin methyl groups associated with Co^{II} and Co^{III} . The large downfield shift for $(\text{TPP})\text{Co}^{\text{II}}$ is caused by its paramagnetism.

There is no exchange at the lowest temperature (-32°C) and the *p*-methyl lines for both oxidation states are sharp. The second set of peaks in Figure 6 falls into the category of slow exchange where the broadening of the lines is already visible, but still much smaller than their separation. The line broadening is defined as the difference between the line width at half height between the exchange-broadened signal (W) and the signal obtained in the absence of exchange (W_0). In the slow-

Figure 6. Temperature dependence of the *p*-methyl line shapes in 90-MHz ^1H NMR spectra of a mixture of $\text{Co}^{\text{II}}\text{TTP}$ and $\text{ClCo}^{\text{III}}\text{TTP}$ in CDCl_3 . exchange region, the line broadening is directly related to the exchange rate constant by the expression in Eq. 29 (W in units s^{-1}).

$$(W - W_0) = 1/(\pi\tau) \quad (29)$$

The application of this equation to the above reaction in tetrahydrofuran gave $k_{\text{exch}} = 8.8 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$

This approach is commonly used for the determination of electron-exchange rate constants. Some of the recent examples include macrocyclic cobalt(III)/cobalt(II) couples [34] of the form $\text{LCo}(\text{OH}_2)\text{X}^{2+}/\text{LCo}(\text{OH}_2)_2^{2+}$ (L is the macrocyclic ligand, X = Cl, Br, and N_3), caged complexes $\text{Co}(\text{act})^{3+}/\text{Co}(\text{act})^{2+}$ [35], the couple $\text{Ru}(\text{en})_3^{3+}/\text{Ru}(\text{en})_3^{2+}$ [35], and copper(II)/copper(I) macrocyclic pentathiaether complexes [36].

The point of coalescence is also related to the exchange rate constants. For equal population of the two peaks, the expression is given in Eq. 30.

$$k_{\text{exch}} = \sqrt{2}\pi\omega_{1/2}^c \quad (30)$$

The term $\omega_{1/2}^c$ is the line width at half-height of the coalesced peak and is equal to the separation between the two peaks in the absence of exchange, $\delta\nu$. The exchange rate constants for the $(\text{TPP})\text{Co}^{\text{II}}/(\text{TPP})\text{Co}^{\text{III}}\text{Cl}$ reaction in CDCl_3 ($k = 2.7 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$) and C_6D_6 ($5.0 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$) were determined by this method [33].

For the fast-exchange region (following the coalescence stage), the line-shape

equation for the two-site system under steady-state conditions was derived [37] from the general line-shape equations, known as Bloch equations. In the absence of proton spin-spin coupling and in the limiting case when $2\pi(\delta\nu)\tau \ll 1$, the simplified expression in Eq. 31 applies.

$$W_{DP} = f_D W_D + f_P W_P + 4\pi f_P f_D (\delta\nu)^2 \tau \quad (31)$$

Here W_{DP} is the difference in the widths between the broadened and final lines, f_D and f_P are the proportions of the reactants present in the diamagnetic and paramagnetic states, respectively, and $\delta\nu$ is the contact shift.

This method was used to determine the rate constants from the line widths of the methyl peaks for the exchange reactions [37] of the couples $\text{Fe}(4,7\text{-Me}_2\text{phen})_3^{3+/2+}$ ($k = 1.4 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ in acetonitrile) and $\text{Fe}(4,4'\text{-Me}_2\text{bpy})_3^{3+/2+}$ ($k = 6 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$). For $\text{Fe}(4,7\text{-ch}_2\text{phen})_3^{3+/2+}$, the line widths of the 5,6-proton peaks were used for the determination of $k_{\text{exch}} = 4.1 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$.

For several other complexes of iron and ruthenium with substituted polypyridine ligands, spin-spin coupling with nearby protons required that the line-shape analysis be done by use of Eqs. 32–36.

$$\text{AI} \propto \frac{\left(1 + \frac{\tau f_D}{T_{2P}} + \frac{\tau f_P}{T_{2D}}\right) S + QR}{S^2 + R^2} \quad (32)$$

$$Q = 2\pi\tau[\Delta\nu + (1 - f_P)\delta\nu] \quad (33)$$

$$S = \frac{\tau}{T_{2D}T_{2P}} + \frac{f_D}{T_{2D}} + \frac{f_P}{T_{2P}} - 4\pi^2\tau(\Delta\nu)(\Delta\nu + \delta\nu) \quad (34)$$

$$R = 2\pi\tau\left[\frac{(\Delta\nu + \delta\nu)}{T_{2D}} + \frac{\Delta\nu}{T_{2P}}\right] + 2\pi(\Delta\nu + f_P\delta\nu) \quad (35)$$

$$\Delta\nu = \nu_D - \nu \quad (36)$$

In these equations, AI is the absorption intensity, T_{2d} and T_{2P} are the transverse relaxation times for the two sites, ν_D is the resonance frequency of the diamagnetic site, and ν is the sweeping frequency. For a mixed second-order rate law, $\tau = 1/\{k_{\text{exch}}([D] + [P])\}$.

This treatment yielded the exchange rate constants for the couples $\text{Fe}(\text{bpy})_3^{3+/2+}$, $\text{Ru}(\text{bpy})_3^{3+/2+}$, $\text{Os}(\text{bpy})_3^{3+/2+}$, and several substituted derivatives. All the rate constants are of the order of 10^6 – $10^7 \text{ M}^{-1} \text{ s}^{-1}$ [37].

Clearly, the expressions in the fast and intermediate exchange region are complex [1, 38, 39], even when valid approximations can be made to simplify the equations. Moreover, a substantial experimental effort is sometimes required before it can be ascertained whether such simplifications are justified. The most reliable and probably the best method for the determination of exchange rate constants in nontrivial cases is the matching of experimental and calculated spectra by computer modeling.

ESR line broadening

“Heroic techniques are not required” [40] for the measurement of electron-transfer rates, even when they are close to the diffusion limit. The principles involved in ESR and NMR line broadening are very similar, but different frequencies are involved and the timescales differ. The ESR method allows the measurement of very short lifetimes (10^{-4} to 10^{-9} s).

As is the case with NMR, the ESR determinations are often carried out in the limit of slow exchange. The fast-exchange limit is difficult to reach experimentally because it requires inordinately high concentration of reagents (≥ 1 M), which exceeds the solubility limit of many compounds. Nonetheless, some electron-exchange constants, such as that between nitrobenzene radical anion and nitrobenzene have been measured in the limit of fast exchange [41]. In this example, the diamagnetic species, nitrobenzene, was used as solvent.

From the researcher’s point of view, the intermediate exchange region often provides the best conditions for line-broadening experiments [42], but data treatment requires computer simulations based on different theoretical models.

In the slow-exchange region, the rate information is obtained from the broadening of hyperfine components, as shown in Figure 7 for the reaction between $(\text{C}_6\text{H}_5\text{Cl})_2\text{Cr}^+$ and $(\text{C}_6\text{H}_5\text{Cl})_2\text{Cr}$ in dimethylsulfoxide, for which $k_{\text{exch}} = 2.0 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ [43].

The reaction between $\text{Cr}(\text{bpy})_3^+$ and $\text{Cr}(\text{bpy})_3$, $k = 1.5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ in dmf, was measured [44] in the slow-exchange limit by use of Eq. 37.

$$k = 2.83 \times 10^6 \sqrt{3\pi} \Delta(\Delta H_{\text{pp}}) / [\text{Cr}(\text{bpy})_3] \quad (37)$$

where $\Delta(\Delta H_{\text{pp}})$ is the exchange-induced increase (in gauss) in the peak-to-peak line width of the first-derivative spectra. The above expression was derived in an earlier study of the electron exchange between naphthalene and naphthalene anions [45]. The factor 2.83×10^6 relates the field in oersteds to the frequency.

A study of several quinone/semiquinone reactions [46] used similar conditions (low-exchange limit) and an in situ photolysis–ESR flow instrument. The chemistry involved in the generation of semiquinones is shown in Eq. 38

where Q^* is the excited quinone and $\text{SQ}^{\bullet-}$ the corresponding semiquinone. The residence time of the solution in the cell was approximately 20 ms. The exchange rate constants k_{exch} in the range $6\text{--}20 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ for various $\text{Q}/\text{SQ}^{\bullet-}$ couples were obtained by use of an equation that is essentially the same as that shown above except for an added line-intensity correction term.

For the examples discussed so far, continuous wave (cw) ESR was utilized, where the magnetic field is swept during the measurement. In the pulsed free induction decay attenuation method [47, 48], the sample in the applied steady field is subjected to a powerful microwave pulse which causes the tipping of the magnetization vector. This method is analogous to pulsed NMR measurements. After the pulse, the

Figure 7. ESR spectra of 5.4×10^{-4} M $(\text{C}_6\text{H}_5\text{Cl})_2\text{Cr}^+$ in DMSO at 22°C . (a) No added $(\text{C}_6\text{H}_5\text{Cl})_2\text{Cr}^0$. (c) Added ca. 0.04 M $(\text{C}_6\text{H}_5\text{Cl})_2\text{Cr}^0$. (e) Added ca. 0.08 M $(\text{C}_6\text{H}_5\text{Cl})_2\text{Cr}^0$. (g) added ca. 0.1 M $(\text{C}_6\text{H}_5\text{Cl})_2\text{Cr}^0$. Panels (b), (d), (f), and (h) are computer simulations of the spectra immediately above them. Reprinted with permission from T. T.-T. Li and C. H. Brubaker, Jr., *J. Organomet. Chem.* 1981, 216, 223. Copyright 1981 Elsevier.

magnetization relaxes to its equilibrium position in a process known as free induction decay (FID). The EPR spectra are obtained by Fourier transformation of extrapolated FID's [49]. This method makes it possible to assign precise intensities and line widths [50] to each radical and was used recently in a study of hydrogen-atom abstraction from 2-propanol by hydrogen and deuterium atoms [49], produced by pulse radiolysis. The electron pulse triggered the ESR pulse unit and the detection system. The width of the microwave pulse was 40 ns, and the delay between electron pulse (duration 15 ns) and the microwave pulse was 0.4 μ s. The rate constants obtained and the associated kinetic isotope effects (kie) are summarized in Eqs 39–42.

1.4 High-Pressure Techniques

In studies of reaction kinetics at different temperatures, the enthalpies (ΔH^\ddagger) and entropies (ΔS^\ddagger) of activation are provided by the Eyring equation, Eq. 43.

$$k = \frac{k_{\text{B}}T}{h} e^{-(\Delta H^\ddagger/RT)} e^{-(\Delta S^\ddagger/R)} \quad (43)$$

These parameters are extremely useful for unraveling reaction mechanisms. The interpretation of ΔH^\ddagger for an elementary step is straightforward—it is the difference in heat contents between the reactants and transition state. The ΔS^\ddagger term, although defined clearly in the equation above, is much less tangible. It describes the change in order (or disorder) of the system and is subject to more freedom in interpretation than ΔH^\ddagger . The situation is not helped by the fact that standard deviations associated with ΔS^\ddagger are usually large, and a straightforward, reasonably quantitative interpretation is possible only at large absolute (positive or negative) values of ΔS^\ddagger .

Another parameter closely related to the disorder of a system, but easier to interpret, is the volume of activation. Also, ΔV^\ddagger can be measured much more precisely than ΔS^\ddagger [51], but special techniques, utilizing high pressure, are needed. It takes 2000–3000 atm to induce a significant change in rate constants and obtain precise

values of ΔV^\ddagger . In comparison, changing the temperature over a range of 20–30 K is sufficient to determine ΔH^\ddagger precisely.

The interpretation of ΔV^\ddagger is concerned with two major contributions to the observed values: the intrinsic changes in volume (caused by changes in bond lengths and angles) and changes in solvation.

Almost every imaginable spectroscopic and electrochemical method have been used for the determination of ΔV^\ddagger . The development of a transportable high pressure unit [52] made such measurements accessible to many laboratories. High-pressure NMR work, however, is more difficult to carry out and requires special equipment [53, 54].

In the transportable unit, pressures up to 2000–4000 atm are generated with a hand-operated mechanical screw pump. Good sealing and lubrication are achieved by use of oil as the pressure medium. The reaction cell is located in a hydrostatic medium (usually water for UV/visible measurements) which is separated from the oil by a separator unit. For the stopped-flow measurements, the complete assembly (drive syringes, observation cell, and the stopping syringe) are placed inside the hydrostatic medium, in which the syringe plungers move to balance the internal and external pressure. The windows of the observation cells are usually made of sapphire or fused silica. Both materials have the required optical transparency coupled with good mechanical properties.

High-pressure effects have so far been studied for a large number of reactions, including several categories of electron transfer: outer-sphere, long-distance (utilizing biological molecules), and photochemical [51]. Surprising results were obtained in the reaction between $\text{Co}(\text{NH}_3)_5\text{X}^{n+}$ ($\text{X} = \text{Cl}^-$, N_3^- , H_2O , etc.) and $\text{Fe}(\text{CN})_6^{4-}$ [55]. Because of the large equilibrium constant for the formation of the precursor complex from the oppositely charged reactants, Eq. 44,

it was possible to separate the volume change for this stage from that for electron transfer, Eq. 45.

The ion-pair formation has an activation volume of close to zero, which is very different from the large positive ΔV^\ddagger expected for the desolvation caused by charge neutralization. The data were rationalized by the consideration of solvent-separated ion pairs.

High-pressure NMR [53, 54, 56] typically utilizes either pressurizable NMR tubes or a high-pressure probe head. The greatest advantage of the pressurizable glass tubes is that they can be used with commercial probes which makes it possible to spin the sample and thus improve the resolution. On the negative side, the thick tube walls reduce the sensitivity and lead to imperfect temperature control. Also, the pressures are usually lower than those obtained with high-pressure probe heads.

The sensitivity is much higher for high-pressure probe heads, in which the RF coil is placed close to the sample tube. A high-pressure high-resolution probe consists of the high-pressure bomb with an NMR insert holding the RF coil and the sample container [53]. Connections to the pressure-transmitting medium and access for temperature-measuring devices are built into the probe. The sample container, which is usually a standard NMR tube, allows pressure transmission and separates the sample from the pressure-transmitting fluid.

A high-pressure probe in combination with a ^{13}C NMR instrument was used recently in a study of self-exchange reactions for several cyanometalate complexes, $\text{Os}(\text{CN})_6^{3-}/\text{Os}(\text{CN})_6^{4-}$, $\text{Mo}(\text{CN})_8^{3-}/\text{Mo}(\text{CN})_8^{4-}$, and $\text{W}(\text{CN})_8^{3-}/\text{W}(\text{CN})_8^{4-}$ [57]. The rate constant k_{exch} was found to be strongly influenced by added cations. Moreover, the values of ΔV^\ddagger were inconsistent with Marcus theory. It was concluded that partially desolvated cations (Li^+ , Na^+ , K^+ , etc.) bridge the reacting anions in the transition state.

1.5 Indirect Methods and Special Cases

1.5.1 Competition Kinetics

Some reactions are difficult to study directly because the required instrumentation is not available or the changes in standard physical properties (light absorption, conductivity etc.) typically used in kinetic measurements are too small to be useful. Competition kinetics can provide important information in such cases. In some situations, the chemistry itself makes direct measurement inconvenient or even impossible. This is the case, for example, in studies of slow reactions of free radicals. Because of the ever-present radical-depleting second-order decomposition reactions, slow reactions of free radicals with added substrates are possible only at very low, steady-state radical concentrations. The standard methods of radical generation (pulse radiolysis and flash photolysis) are not useful in such cases, because they require micromolar levels of radicals for a measurable signal. The self-reactions usually have $k \geq 10^9 \text{ M}^{-1} \text{ s}^{-1}$, so that the competing reactions must have a pseudo-first-order rate constant of 10^4 s^{-1} or higher (or equivalent, if conditions are not pseudo-first order) to be observed. Competition experiments, on the other hand, can handle much lower rate constants, as described later for some reactions of $^{\bullet}\text{C}(\text{CH}_3)_2\text{OH}$ radicals with transition metal complexes.

Depending on the timescales involved and the nature of the chemical reaction, the kinetic information can be obtained from product distribution, luminescence quenching, or kinetic measurements in the presence of a kinetic probe or a radical precursor. Inevitably, however, the result is obtained as a *relative* rate constant. The conversion to the absolute value requires that the rate constant for the competing process(es) be known.

Competition between intramolecular and intermolecular reactions of free radicals has been used extensively in kinetic and mechanistic studies. The rate constants for

the cyclization, ring opening, or β -scission of a number of radicals are now available. These "radical clock" [58] reactions cover a range of over 11 orders of magnitude in rate constants [58–60] and can be used to time the reactions with desired substrates on almost any timescale.

In addition to their role in kinetics, radical clocks also serve an important mechanistic function in that the formation of the rearranged product provides evidence for radical involvement in the first place. The incorporation of a ring-opening probe into the substrate, followed by product analysis—specifically, a search for rearranged product—has been used in mechanistic studies of the action of some enzymes, such as cyt P450 [61] and methane monooxygenase [62].

The cyclization of 1-hexenyl radical as a clock reaction has been used in large number of cases, including hydrogen-atom abstraction from the phenolic group of α -tocopherol (vitamin E, EOH) [63]. The radicals were generated in the presence of EOH at 70°C and the products, 1-hexene and methylcyclopentane, determined after the completion of the reaction. (See Eqs. 46–48.)

The ratio of the two products is given by Eq. 49.

$$\frac{[\text{1-hexene}]}{[\text{methylcyclopentane}]} = \frac{k_{\text{EOH}}[\text{EOH}]}{k_c} \quad (49)$$

A plot of the left-hand side of the equation against [EOH] yielded k_{EOH}/k_c , which was combined with the known k_c ($1.1 \times 10^6 \text{ s}^{-1}$ at 70°C) to give $k_{\text{LOH}} = 1.7 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$.

Product analysis has also been utilized in studies of nonradical reactions where the competition is usually established between two bimolecular paths for the consumption of the limiting reagent. The reduction of $\text{Cr}_{\text{aq}}^{2+}$ by $\text{V}_{\text{aq}}\text{O}^{2+}$, Eq. 50, is fast and accompanied by only a small absorbance change [64].

The competing reaction of $\text{Co}(\text{NH}_3)_5\text{F}^{2+}$ with $\text{Cr}_{\text{aq}}^{2+}$, Eq. 51, has $k_{\text{Co}} = 9 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$, and produces $\text{Co}_{\text{aq}}^{2+}$, which can be conveniently determined by spectrophotometry after conversion to the intensely blue $\text{Co}(\text{NCS})_4^{2-}$.

In the experiment, limited amounts of $\text{Cr}_{\text{aq}}^{2+}$ were either injected or generated in situ in the presence of large, known amounts of $\text{V}_{\text{aq}}\text{O}^{2+}$ and $\text{Co}(\text{NH}_3)_5\text{F}^{2+}$. The concentration of $\text{Co}_{\text{aq}}^{2+}$ produced was related to the total concentration of the product ($[\text{V}_{\text{aq}}^{3+}] + [\text{Co}_{\text{aq}}^{2+}] = [\text{Cr}_{\text{aq}}^{2+}]_{\text{total}}$) by Eq. 52

$$[\text{Co}_{\text{aq}}^{2+}]_{\text{inf}}/[\text{Cr}_{\text{aq}}^{2+}]_{\text{total}} = 1 + (k_{\text{VO}}/k_{\text{CoF}})([\text{V}_{\text{aq}}\text{O}^{2+}]_{\text{av}}/[(\text{NH}_3)_5\text{CoX}^{2+}]_{\text{av}}) \quad (52)$$

which yielded $k_{\text{V}} = 1.4 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$.

Controlled scission of the Cr–C bond in the presence of a substrate was used to determine the kinetics of reduction of a number of transition metal complexes with organic free radicals. The reaction scheme for $\text{Co}(\text{NH}_3)_5\text{py}^{2+}$ [65] is shown in Eqs. 53–55.

The organochromium complex disappears in two parallel processes: irreversible acidolysis (k_{a}) and reversible homolysis (k_{h}). The kinetics, Eq. 56, are determined by k_{a} and the competition for the organic radical between $\text{Co}(\text{NH}_3)_5\text{py}^{2+}$ and a controlled excess of $\text{Cr}_{\text{aq}}^{2+}$.

$$\begin{aligned} & -d[\text{Cr}_{\text{aq}}\text{C}(\text{CH}_3)_2\text{OH}^{2+}]/dt \\ & = \left(k_{\text{a}} + \frac{k_{\text{h}}k_{\text{R}}[\text{Co}^{\text{III}}]}{k_{\text{R}}[\text{Co}^{\text{III}}] + k_{\text{Cr}}[\text{Cr}_{\text{aq}}^{2+}]} \right) [\text{Cr}_{\text{aq}}\text{C}(\text{CH}_3)_2\text{OH}^{2+}] \end{aligned} \quad (56)$$

The fit of the data to the above equation yielded the composite rate constant $k_{\text{Cr}}/k_{\text{h}}k_{\text{R}}$, which was combined with the known values for k_{h} and k_{Cr} to yield $k_{\text{R}} = 1.2 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$. This method was used to measure rate constants as low as $5 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ [66], which is clearly outside the range of direct determinations.

Luminescence quenching is limited to the reactions of excited states. By use of spectrofluorometers, luminescence intensities can be monitored precisely. As an example, let us consider the uranyl(VI) ion which has a long-lived, strongly luminescent excited state, $^*\text{U}_{\text{aq}}\text{O}_2^{2+}$ [67]. In the absence of added reagents, the decay to the ground state takes place by physical quenching (k_{phys}) and light emission (k_{em}), so that the quantum yield (Φ_0) is given by Eq. 57.

$$\Phi_0 = k_{\text{em}}/(k_{\text{phys}} + k_{\text{em}}) \quad (57)$$

In the presence of a quencher, say methanol, the chemical reaction of Eq. 58

contributes to the loss of $^*\text{U}_{\text{aq}}\text{O}_2^{2+}$ and diminishes the quantum yield, Eq. 59.

$$\Phi = k_{\text{em}} / (k_{\text{phys}} + k_{\text{em}} + k_{\text{MeOH}}[\text{MeOH}]) \quad (59)$$

Fluorescence intensities (F), which are related to quantum yields through the intensity of absorbed light (I_{abs}), Eq. 60,

$$F = \Phi I_{\text{abs}} \quad (60)$$

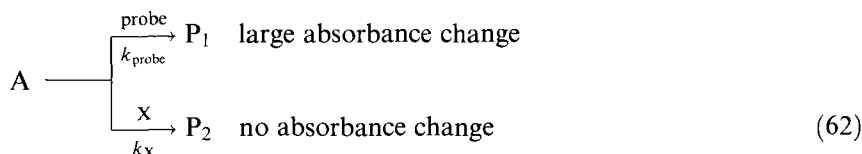

are directly related to the rate constants for all the processes involved, Eq. 61,

$$\begin{aligned} F_0/F &= (k_{\text{phys}} + k_{\text{em}} + k_{\text{MeOH}}[\text{MeOH}]) / (k_{\text{phys}} + k_{\text{em}}) \\ &= 1 + \tau_0 k_{\text{MeOH}}[\text{MeOH}] \end{aligned} \quad (61)$$

where $\tau_0 = (k_{\text{phys}} + k_{\text{em}})^{-1}$.

A plot, known as the Stern–Volmer plot, of F_0/F against $[\text{MeOH}]$ yielded $\tau_0 k_{\text{MeOH}} = 7.2$ [67]. By use of the independently known τ_0 (1.2×10^{-6} s), one obtains $k_{\text{MeOH}} = 6 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$. Similar determinations were carried out for a number of alcohols and other reducing compounds. Many of the rate constants were later determined directly by laser-flash photolysis [68]. Excellent agreement between the two methods was found.

If the reaction of interest does not have a measurable monitoring signal, a parallel reaction accompanied by a large change in the desired physical property, usually absorbance, may be employed as a kinetics tool [69, 70]. Under such conditions, the scheme in Eq. 62 applies

The expression for the loss of the limiting reagent A is given as the sum of all the contributing reactions, Eq. 63.

$$-d[\text{A}]/dt = (k_{\text{probe}}[\text{probe}] + k_{\text{X}}[\text{X}])[\text{A}] \quad (63)$$

In practice, the composite rate constant is corrected for the independently-measured rate constant for the probe reaction. The precision improves when the kinetic contribution from the k_{X} path is as large as possible while still retaining an acceptable absorbance change provided by the probe reaction. This approach is used widely in laser-flash photolysis studies of radical reactions, which are described in detail in one of the following chapters.

1.5.2 Exchange Reactions

Exchange reactions represent a special case in chemical kinetics, because they lead to no net chemical change. The physical properties of the system remain unchanged; this requires a special approach for the monitoring of kinetics. For fast reactions, NMR and ESR line broadening are extremely valuable for obtaining the exchange rate constant k_{exch} , as already described. For slower reactions, one of the exchanging partners is isotopically labeled. The reaction is allowed to proceed for a pre-determined period of time and is then quenched. The products are separated and the extent of label scrambling is determined experimentally.

An early example is provided by the electron-exchange reaction in Eq. 64 [71].

The permanganate ion was labeled with ^{54}Mn . The separation of MnO_4^- for kinetic determinations was achieved by co-precipitation with tetraphenylarsonium perrhenate, and the activity was determined with a scintillation counter. The rate constant, $k_{\text{exch}} = 710 \text{ M}^{-1} \text{ s}^{-1}$ at 273 K, was obtained by fitting of the data to Eq. 65

$$k_{\text{exch}} = \ln 2 / \{t_{1/2}([\text{MnO}_4^-] + [\text{MnO}_4^{2-}])\} \quad (65)$$

where $t_{1/2}$ represents the half-life for electron exchange.

In a similar study, ^{59}Fe -labeled $\text{Fe}(\text{H}_2\text{O})_6^{3+}$ was allowed to exchange with $\text{Fe}(\text{H}_2\text{O})_6^{2+}$ in the presence of chloride ions [72]. The reaction was quenched by the addition of 2,2'-bipyridine which complexes Fe^{II} , and the activity of ^{59}Fe in the complex was determined by scintillation counting. It was found that most of the exchange takes place by the reaction of Eq. 66

which has a rate constant of $57.6 \text{ M}^{-1} \text{ s}^{-1}$ at an ionic strength of 3.0 M.

The determination of the self-exchange rate for the couple $\text{O}_2/\text{O}_2^{\bullet-}$ was an important development in view of the failure of Marcus–Hush theory to yield consistent results. The values obtained by the latter approach varied with the chemical system chosen and covered a range of over 16 orders of magnitude [73].

The experimental determination was carried out by use of ^{18}O as a probe [74]. The labeled $\text{O}_2^{\bullet-}$ was allowed to exchange with $^{32}\text{O}_2$ at high pH (Eq. 67),

which ruled out the involvement of the conjugate acid HO_2 ($\text{p}K_a = 4.7$) in the exchange reaction and also slowed down the decay of $\text{O}_2^{\bullet-}$ by disproportionation. The exchange was quenched by lowering of the pH, a process that induced rapid disproportionation of $\text{O}_2^{\bullet-}$, Eq. 68.

The solution was purged with argon and catalase was added to initiate yet another disproportionation reaction, Eq. 69.

The amount of ^{18}O in the newly produced O_2 was determined by mass spectroscopy and the exchange rate constant, $k_{\text{exch}} = 450 \text{ M}^{-1} \text{ s}^{-1}$, was calculated by use of the expression in Eq. 70

$$\ln \left\{ \frac{{}^{32}\text{O}_2 + {}^{36}\text{O}_2}{{}^{36}\text{O}_2} \right\} = k_{\text{exch}}[\text{O}_2]t \quad (70)$$

where $[\text{O}_2]$ represents the concentration of $^{32}\text{O}_2$ present during the exchange reaction.

Acknowledgments

This work was supported by the U.S. Department of Energy, Office of Basic Energy Sciences, Division of Chemical Sciences under contract W-7405-Eng-82. I am indebted to Dr. Peter Metelski for insightful comments and help with some figures, and to Drs. Steve Veysey and Rudi van Eldik for helpful discussions.

2 Electrochemical Techniques

Steen Uttrup Pedersen and Kim Daasbjerg

2.1 Electrochemical Techniques

The distinct feature of electrochemical methods is that they can be used to obtain information about the energetics and kinetics of a wealth of reactions, including both heterogeneous and homogeneous processes. In this sense, the electrode is a unique tool, because it can be used to generate or activate molecules and at the same time detect, either directly or indirectly, intermediates formed during this electrochemical activation process. The characteristic time window of the different electrochemical techniques may range from nanoseconds to several days, so when used in combination, they offer a versatile methodology that allows the study of many kinds of chemical reactions.

In the present chapter, the main focus will be on the most common electrochemical techniques and methods used in the elucidation of reaction mechanisms. In general, it is possible from a quantitative analysis of the relation between current and potential to formulate even complex reaction mechanisms that incorporate preceding and/or follow-up reactions. A part of this text is devoted specifically to the description of the procedures used in the extraction of standard potentials and rate constants once the mechanism is known. However, before a discussion of the individual techniques can be accomplished, an introduction to the basic concepts in electrochemistry seems appropriate. For obvious reasons, this part can only be of limited length in a chapter, and for the reader who would appreciate a more detailed description of the basic principles, we recommend the book of Bard and Faulkner [1].

2.1.1 Introduction

One of the most fundamental equations used in electrochemistry is the Nernst equation (Eq. 1) that relates the electrode potential, E , with the concentrations of the two species O and R in the equilibrium process shown in Eq. 2.

$$E = E_{\text{O}}^{\circ} + \frac{RT}{nF} \ln \left(\frac{C_{\text{O,eq}}}{C_{\text{R,eq}}} \right) \quad (1)$$

The parameter R is the gas constant, T is the temperature, F is the Faraday constant and n is the number of electrons consumed in the electron transfer step (Eq. 2). The standard potential, E_{O}° of the redox couple O/R is defined as the reduction potential of O when the activity coefficients for both O and R are equal to one. Once E_{O}° is known, the electrode potential can be used to measure concentrations in solutions or to calculate equilibrium constants, K_{eq} , for redox equilibria (Eq. 3) involving two or more redox couples as shown in Eq. 4.

$$\Delta E^{\circ} = E_{\text{O}_1}^{\circ} - E_{\text{O}_2}^{\circ} = \frac{RT}{nF} \ln \left[\frac{C_{\text{R}_1,\text{eq}} C_{\text{O}_2,\text{eq}}}{C_{\text{O}_1,\text{eq}} C_{\text{R}_2,\text{eq}}} \right] = \frac{RT}{nF} \ln K_{\text{eq}} = - \frac{\Delta G^{\circ}}{nF} \quad (4)$$

A very important point in electrochemistry is that the exchange of electrons between an electrode and an reactant, that is, an oxidant or reductant, can only take place at the electrode surface. In the Nernst equation, this fact might seem to be partly obscured by the use of equilibrium concentrations, but as no net reaction occurs at equilibrium, the surface concentrations must be equal to the equilibrium concentrations. In most applications of electrochemistry, the electrode potential is varied, to achieve surface concentrations $C_{\text{O}}(0, t)$ that are different from the concentrations found far from the electrode surface, that is, in the bulk (C_{O}°). In other words, the electrode potential is used for creating a nonequilibrium situation where the dynamic response of the chemical system can be examined.

Because the exchange of electrons occurs at the electrode surface, the rate of any electrochemical process will depend on $C_{\text{O}}(0, t)$ and not the concentration in the bulk of the solution, C_{O}° . This is a distinct difference between an electrode reaction that is a heterogeneous process and a homogeneous process. Besides $C_{\text{O}}(0, t)$, the rate of an electrode reaction also depends on the electrode potential which can be varied by increase or decrease of the charge on the electrode surface. Formally, the electrode potential is defined as the work required for the transfer of a positive charge from infinity to the electrode surface. For a reduction process, the electron is always transferred from the electrode to the oxidant present at the surface, and the speed of this process can be increased by “pumping” more electrons onto the electrode surface, and in this manner raise the energy. Thus, the potential is almost always negative for a reduction process and the rate increases when the electrode potential is lowered (i.e., made even more negative). This dependency of the pertinent rate constant k_{red} on the electrode potential is, of course, also true for an oxidation process, with the modification that the rate constant k_{ox} increases if the potential becomes more positive by the “drawing away” of electrons from the electrode surface. The explicit equations for the two rate constants k_{red} and k_{ox} are given in Eqs. 5 and 6, respectively, where α denotes the so-called symmetry factor and k° is the standard heterogeneous rate constant.

$$k_{\text{red}} = k^{\circ} \exp \left[\frac{-\alpha n F}{RT} (E - E_{\text{O}}^{\circ}) \right] \quad (5)$$

$$k_{\text{ox}} = k^{\circ} \exp \left[\frac{(1 - \alpha) n F}{RT} (E - E_{\text{O}}^{\circ}) \right] \quad (6)$$

The “pump” or control unit for adjustment of the surface charge at the electrode is usually a potentiostat that is capable of keeping the electrode potential at a fixed value relative to a reference electrode. Alternatively, the amount of charge can be adjusted by control of the current rather than the potential; this can be achieved by a suitable power supply.

The current i measured at any value of the potential E for a given electrode reaction (Eq. 2) provides a direct measure of the rate of the charge-transfer process occurring at the electrode surface. It can be quantified as shown in Eq. 7

$$i = nFA D_{\text{O}} \left(\frac{\partial C_{\text{O}}}{\partial x} \right)_{x=0} = nFA [k_{\text{red}} C_{\text{O}}(0, t) - k_{\text{ox}} C_{\text{R}}(0, t)] \quad (7)$$

where A is the area of the electrode surface, D_{O} is the diffusion coefficient of O and $\left(\frac{\partial C_{\text{O}}}{\partial x} \right)_{x=0}$ is the concentration gradient of O at the surface. Note that the presence of the two opposing terms in Eq. 7 is a reflection of the fact that both a reduction and oxidation process take place in the reaction (Eq. 2). Combining Eqs. 5–7 then results in the fundamental current potential equation given in Eq. 8.

$$i = nFA k^{\circ} \left\{ C_{\text{O}}(0, t) \exp \left[\frac{-\alpha n F}{RT} (E - E_{\text{O}}^{\circ}) \right] - C_{\text{R}}(0, t) \exp \left[\frac{(1 - \alpha) n F}{RT} (E - E_{\text{O}}^{\circ}) \right] \right\} \quad (8)$$

The different parameters incorporated in Eq. 8 can be divided into two groups. The first group consists of the standard rate constant, k° , the symmetry factor α , the number of electrons transferred, n , and the standard potential E_{O}° , all of which are intrinsic parameters specifically related to the reaction system under investigation. The electrode area, A , the surface concentrations, $C_{\text{O}}(0, t)$ and $C_{\text{R}}(0, t)$, the temperature, T , and the electrode potential, E , belong to the second group of experimental parameters that can be varied externally. In particular, E has an enormous influence on the balance between the reduction and oxidation processes, as expressed mathematically by its presence with opposite signs in the exponential terms of Eq. 8. Apparently, any size of the current i can thus be obtained simply through an adjustment of E . However, this is only true within some limits. First of all, the absolute variation of the electrode potential is set by the characteristic potential window of the medium, that is, if too extreme potentials are applied, decomposition of the medium will occur either by reduction or oxidation of the solvent or the supporting electrolyte. But even at less extreme potentials and especially if k° is large, the limiting and rate-controlling step may become transport of the substrates

to and from the electrode surface rather than the electrode reaction. Thirdly, the situation may be complicated by the presence of chemical reactions involving O and R. For instance, if the species R is involved in follow-up chemistry that consumes electrons, the total number of electrons used are higher than n . In other words, the current which is proportional to the total number of electrons consumed is also dependent on the fate of R.

In summary, the current i is therefore determined by a) heterogeneous kinetics in terms of $E - E_O^\circ$, α , and k° , b) mass transport as expressed by $C_O(0, t)$ and $C_R(0, t)$, and c) homogeneous kinetics. Each of these three points is discussed in further detail in the following sections.

2.1.2 Heterogeneous Kinetics

The equilibrium situation is characterized by $E = E_{\text{eq}}$, when $i = 0$, $C_O(0, t) = C_O^*$ and $C_R(0, t) = C_R^*$, that is, the two terms in Eq. 8 become equal and cancel each other. The exchange current, i_0 , is defined as being equal to one of the two terms, as stated in Eq. 10. This equation can be rewritten as shown in Eq. 11 if the Nernst equation (Eq. 1) is employed.

$$\begin{aligned} i_0 &= nFAk^\circ C_O^* \exp\left[\frac{-\alpha nF}{RT}(E_{\text{eq}} - E_O^\circ)\right] \\ &= nFAk^\circ C_R^* \exp\left[\frac{(1-\alpha)nF}{RT}(E_{\text{eq}} - E_O^\circ)\right] \end{aligned} \quad (10)$$

$$i_0 = nFAk^\circ C_O^{*(1-\alpha)} C_R^{*\alpha} \quad (11)$$

If Eq. 11 is inserted into the current-potential equation (Eq. 8), the so-called current-overpotential equation results (Eq. 12), where the overpotential η is defined as the potential relative to the equilibrium potential, $\eta = E - E_{\text{eq}}$.

$$i = i_0 \left\{ \frac{C_O(0, t)}{C_O^*} \exp\left[\frac{-\alpha nF\eta}{RT}\right] - \frac{C_R(0, t)}{C_R^*} \exp\left[\frac{(1-\alpha)nF\eta}{RT}\right] \right\} \quad (12)$$

On the assumption that the surface concentrations of O and R will not differ significantly from the bulk concentrations, Eq. 12 can be reduced to the Butler-Volmer equation shown in Eq. 13. For very small variations of η , both exponential functions can be linearized, and the simple expression given in Eq. 14 results.

$$i = i_0 \left\{ \exp\left[\frac{-\alpha nF\eta}{RT}\right] - \exp\left[\frac{(1-\alpha)nF\eta}{RT}\right] \right\} \quad (13)$$

$$i = -i_0 \left(\frac{nF\eta}{RT} \right) \quad (14)$$

Electrode reactions are called reversible when the surface concentrations are adjusted quickly in accordance with the Nernst equation upon a change in E . In many experiments this requirement of O and R being constantly in equilibrium with the electrode is hard to fulfil, since the heterogeneous charge transfer is accompanied by both structural and solvent reorganization. The larger the reorganization energy, the slower the charge transfer process becomes, i.e. k° is diminished. The term reversible is therefore used for electrode reactions with a large k° . Another important requirement for reversibility is that the surface concentrations of O and R are not perturbed by the presence of homogeneous reactions during the electrochemical measurement.

Should the electrode reaction be associated with a low k° value, a significant overpotential is required for any reaction to be accomplished. Hence, one of the terms in Eq. 8 can be neglected, depending on the sign of the overpotential, and the electrode reaction is then referred to as an irreversible process. At low values of E , the oxidation term in Eq. 8 is negligible; this leads to Eq. 15. On the other hand, at high potentials the reduction term can be neglected, with Eq. 16 resulting.

$$\begin{aligned} i &= nFAk^\circ C_O(0, t) \exp\left[\frac{-\alpha nF}{RT}(E - E_O^\circ)\right] \\ &= i_0 \left\{ \frac{C_O(0, t)}{C_O^*} \exp\left[\frac{-\alpha nF\eta}{RT}\right] \right\} \end{aligned} \quad (15)$$

$$\begin{aligned} i &= nFAk^\circ C_R(0, t) \exp\left[\frac{(1 - \alpha)nF}{RT}(E - E_O^\circ)\right] \\ &= i_0 \left\{ \frac{C_R(0, t)}{C_R^*} \exp\left[\frac{(1 - \alpha)nF\eta}{RT}\right] \right\} \end{aligned} \quad (16)$$

Consider a reduction process, where $C_O(0, t) \approx C_O^*$; then Eq. 15 can be transformed to the Tafel equation given in Eq. 17.

$$\log i = \log i_0 - \frac{\alpha nF\eta}{2.3RT} \quad (17)$$

In a Tafel plot, the logarithm of the current is plotted against η , as illustrated in Figure 1. Note that the slope is equal to $-\alpha nF/2.3RT$ and the intercept corresponds to $\log i_0$. From these values, k° can be determined with Eq. 11. Tafel plots are often employed in corrosion studies, since k° is usually small and the condition $C_O(0, t) \approx C_O^*$ can be accomplished by simply stirring the solution. Deviations from the idealized Tafel behavior are seen at large $|\eta|$, where $C_O(0, t)$ becomes significantly smaller than C_O^* .

An intermediate situation between the reversible and irreversible cases arises for relatively slow charge-transfer processes, where the Nernst equation does not apply. On the other hand, k° is not so small that either of the two terms in Eq. 8 can be neglected. Such an electrode process is denoted quasi-reversible.

Figure 1. Tafel plot for anodic and cathodic branches of the current–overpotential curve for $O + ne \rightleftharpoons R$ ($n = 1$, $\alpha = 0.5$, $T = 25^\circ\text{C}$, and $i_0 = 10^{-8}$ A).

2.1.3 Mass Transport

The flux, $J_O(x, t)$, is defined as the transport of O per unit area ($\text{mol s}^{-1} \text{cm}^{-2}$). It can be divided into three components, diffusion, migration, and convection, as originally expressed in the Nernst–Planck equation, written for one-dimensional mass transport along the x -axis in Eq. 18.

$$\begin{aligned} J_O(x, t) &= -\frac{D_O C_O(x, t)}{RT} \nabla \mu_O^{\text{el}}(x, t) + v(x, t) C_O(x, t) \\ &= -D_O \frac{\partial C_O(x, t)}{\partial x} - \frac{z_O F}{RT} D_O C_O(x, t) \left(\frac{\partial \phi(x, t)}{\partial x} \right) + v(x, t) C_O(x, t) \end{aligned} \quad (18)$$

$$\mu_O^{\text{el}}(x, t) = \mu_O^\circ + RT \ln C_O(x, t) + z_O F \phi(x, t) \quad (19)$$

The parameter D_O is the diffusion coefficient ($\text{cm}^2 \text{s}^{-1}$), $\mu_O^{\text{el}}(x, t)$ is the electrochemical potential defined in Eq. 19, $v(x, t)$ is the velocity (cm s^{-1}) of a volume element in the solution along the x -axis, z_O is the charge of O, μ_O° is the standard chemical potential, and $\phi(x, t)$ is the potential. The convection expressed by $v(x, t) C_O(x, t)$ should be taking into account only if the solution is, for example, stirred so that it moves relative to the electrode surface. The diffusion and migration terms arise because of non-uniformity in $\mu_O^{\text{el}}(x, t)$. Specifically, the diffusion is caused by concentration gradients, that is, when $\frac{\partial C_O(x, t)}{\partial x} \neq 0$, and the migration is

caused by the potential gradient $\frac{\partial \phi(x, t)}{\partial x}$, which creates an electric field. Whereas convection can be avoided if the solution is not stirred, migration and diffusion will always take place in an electrochemical cell, although the former process pertains

only to charged species. The effect of migration on $J_O(x, t)$ can largely be eliminated by the addition of a large excess of an electroinactive salt, the supporting electrolyte. In most electroanalytical experiments, a 100-fold excess of supporting electrolyte relative to substrate, together with the absence of stirring, will ensure that the only kind of mass transport to consider is the diffusion of the electroactive material to the electrode surface. In that instance, the Nernst–Planck equation is simplified to the expression given in Eq. 20, which is better known as Fick's first law.

$$-J_O(x, t) = D_O \frac{\partial C_O(x, t)}{\partial x} \quad (20)$$

The current i is given as the flux at the electrode surface, $J_O(0, t)$, integrated over the total electrode area, A , as expressed in Eq. 21.

$$i(t) = -nFAJ_O(0, t) = nFAD_O \left(\frac{\partial C_O(x, t)}{\partial x} \right)_{x=0} \quad (21)$$

A second equation essential for the description of processes controlled by diffusion is Fick's second law (Eq. 22) which states that concentration changes occurring at a specific point in a solution depends on the difference between the fluxes in and out of this point.

$$\frac{\partial C_O(x, t)}{\partial t} = D_O \frac{\partial^2 C_O(x, t)}{\partial x^2} \quad (22)$$

In other words, the law describes the time development in the concentration profiles. Note that Fick's two laws have been written in forms that apply to one-dimensional mass transport processes, but the extension of the equations to three dimensions is straightforward.

Let us now consider the diffusion process of O in the redox couple O/R in closer details. The oxidized species O will be reduced to R at the electrode surface when the applied potential E is smaller than E_O° . This diminishes the concentration of O near the electrode surface and a so-called diffusion layer is formed where $C_O(x, t)$ is less than C_O^* . Thus, the reduction process taking place at the electrode surface creates concentration gradients in the solution. The thickness of the diffusion layer, δ , increases with time and as long as the electrode dimension is large compared to δ , the diffusion will be perpendicular to the electrode surface. Diffusion is said to be planar (or one-dimensional) and δ depends on \sqrt{t} as stated in Eq. 23.

$$\delta = \sqrt{2D_O t} \quad (23)$$

Inserting a realistic value of D_O of $10^{-5} \text{ cm}^2 \text{ s}^{-1}$ in Eq. 23 shows that the value of δ after 5 s will be 0.01 cm ($= 10^6 \text{ \AA}$), which is large on molecular scale but small compared to the normal dimensions of the electrochemical cell. The diffusion layer can never grow to infinity because natural convection in terms of vibrations, tem-

perature and density gradients will tend to preclude any further development in the concentration gradients. Under normal conditions, the maximum value of δ is attained after approximately 5 s, and from then on, a steady-state situation is reached with no further changes in the size of δ ($= 0.01$ cm) and the shape of the concentration profiles. Planar or one-dimensional diffusion will always prevail for an electrode, as long as the radius is about 10 times larger than δ (i.e., radius > 1 mm). However, for smaller electrodes, material may also diffuse to the electrode surface from other directions, and then diffusion is said to be nonplanar or spherical. Obviously, the spherical versions of Fick's two laws should then be employed in the description of the diffusion process.

The final point we would like to emphasize is that the diffusion layer should never be confused with the double layer. The double layer arises because the charge on the electrode is counterbalanced by ions of opposite charge that are specifically adsorbed at the electrode surface. Such a "construction" resembles a capacitor and gives rise to double-layer capacitance, which will be described in detail later on. The thickness of the double layer is only a few Å, much smaller than δ .

2.1.4 Homogeneous Kinetics

Homogeneous reactions preceding or following the charge-transfer process at the electrode surface may substantially influence the current measured. Obviously, if any of the species involved in the chemical reactions are electroactive and can be reduced or oxidized, the total number of electrons consumed is going to be different from the number of electrons used in the reduction of O to R. However, even if the species should be non-electroactive, the current measured at a given value of E is affected by the presence of chemical reactions, as they may shift the charge-transfer equilibrium. From a quantitative point of view, a detailed knowledge of the mechanism is required for assessing the exact influence of such reactions on the response of a given electrochemical technique. Specific examples illustrating these features will be provided along with a description of the different electrochemical techniques (see Sections 2.2 and 2.3). At this point, however, it seems appropriate to introduce the simple nomenclature used in the description of electrochemical reaction schemes where both heterogeneous and homogeneous steps are mixed. A heterogeneous step is indicated by E, whose subscript characterizes the process as being either reversible (r), irreversible (i) or quasi-reversible (q). Homogeneous reactions are denoted by the letter C, with subscript numbers and letters differentiating between first-order (1), second-order (2), reversible (r), and irreversible (i) processes. An E_rC_i mechanism thus consists of the reactions shown in Eqs. 24 and 25, where Y denotes an electroinactive species.

E_rC_i :

A C_iE_r mechanism corresponds to the reactions depicted in Eqs. 26 and 27.

C_iE_r :

A mechanism as shown in Eqs. 28 and 29 where the electroactive substrate O is regenerated in the homogeneous step is called catalytic, and C is then marked with a prime. The reaction is not genuinely catalytic, because electrons are consumed, but it is catalytic in the sense that the redox couple O/R is not consumed.

E_rC' :

Unfortunately, this simple nomenclature is not used consistently in the electrochemical literature and it is usually discarded when more complicated mechanisms need to be distinguished. One example is the $E_rC_iE_r$ mechanism shown in Eqs. 30–32 and the related DISP mechanism depicted in Eqs. 30, 31, and 33 which both may occur if $E_{O_2}^\circ > E_{O_1}^\circ$. In general, the $E_rC_iE_r$ mechanism prevails if k_1 for Eq. 30 is larger than 10^7 s^{-1} , since O_2 is then formed so close to the electrode surface that it can be further reduced in a second heterogeneous step (Eq. 32). For smaller values of k_1 , on the other hand, O_2 will be formed so distant from the electrode that it rather reacts with R_1 in a homogeneous electron-transfer reaction (Eq. 33) [2, 3], that is, the DISP mechanism. In a few publications, the DISP mechanism has been given the abbreviation ECE_h , where the subscript “h” in E_h emphasizes the homogeneous nature of the electron-transfer step.

$E_rC_iE_r$:

DISP:

Eq. 30 + Eq. 31

Trivial names such as DIM1 and DIM2 are also often applied for mechanism EC_2 involving the formation of dimers. In the DIM1 mechanism, two R molecules dimerize, while in the DIM2 mechanism, coupling between R and O is followed by further reduction of the adduct RO by R .

2.2 Potential-Step Experiments

2.2.1 Chronoamperometry

One of the simplest experiments employed in electrochemistry is chronoamperometry (CA). In CA, the electrode potential is changed abruptly from a potential with no current flow to a potential where the surface concentration of O becomes zero. If only O is initially present in the cell, and homogeneous kinetics, migration and convection can be disregarded (i.e., the supporting electrolyte is in 100-fold excess and there is no stirring of the solution), the experiment can be described by the following equations (Eqs. 34–38).

$$\text{Fick's second law:} \quad \frac{\partial C_O(x, t)}{\partial t} = D_O \frac{\partial^2 C_O(x, t)}{\partial x^2} \quad (34)$$

$$\text{Initially:} \quad t = 0, \quad C_O(x, 0) = C_O^*; \quad C_R(x, 0) = 0 \quad (35)$$

$$\text{Far from the electrode:} \quad x \rightarrow \infty, \quad C_O(x, t) = C_O^*; \quad C_R(x, t) = 0 \quad (36)$$

$$\text{Electrode surface:} \quad x = 0, \quad C_O(0, t) = 0; \quad C_R(0, t) = C_O^* \quad (37)$$

$$\text{Fick's first law:} \quad i(t) = nFAD_O \left(\frac{\partial C_O(x, t)}{\partial x} \right)_{x=0} = -nFAD_R \left(\frac{\partial C_R(x, t)}{\partial x} \right)_{x=0} \quad (38)$$

Since the surface concentration of O becomes zero (Eq. 37), the rate of the reduction of O will be mass-transport-controlled or rather diffusion-controlled, as the migration and convection terms can be neglected. Thus, the experiment can be described by use of Fick's first and second laws (Eqs. 38 and 34, respectively). The substrate O is the only species initially present in the cell (Eq. 35) and because the electrode area A is small compared to the cell volume V in electroanalytical experiments, the bulk concentration can be assumed to be unchanged during the experiment (Eq. 36). Should a preparative conversion of O to R be the goal, a large A/V ratio would have been desirable. Equations 34–38 can be solved with the Laplace transformations; this affords the Cottrell equation (Eq. 39).

$$i = \frac{nFA\sqrt{D_O}C_O^*}{\sqrt{\pi t}} \quad (39)$$

As seen, the current i recorded depends on $t^{-1/2}$; this reflects the increase in the thickness of the diffusion layer δ as a function of $t^{1/2}$, as expressed in Eq. 23. A typical CA experiment is shown in Figure 2. When normal microdisc electrodes with diameters ranging from 0.1 to 3 mm are used in the CA technique, the useful time range is 1 ms to 5 s. For step times shorter than 1 ms, the double-layer charging current would contribute significantly to the measured current. The upper time limit is set by the point where the diffusion layer has grown so large that spherical

Figure 2. Chronoamperometric experiment for $O + e \rightleftharpoons R$: a) concentration profiles are shown after 1, 10, 100, and 1000 ms. The concentration gradient at the electrode surface ($x = 0$) is seen to decrease with time; b) plot of the current i vs time t is shown in the interval 0–1000 ms. The current decreases as a function of $t^{-1/2}$.

diffusion no longer can be neglected, and the current has become time-independent. Natural convection may also contribute to the mass transport for large step times.

Perhaps the most prominent feature of the CA technique is that it can be performed on any chemical system, regardless of the value of k° and α , as long as $C_O(0, t) = 0$. For a reversible electrode reaction this condition can easily be fulfilled, as $C_O(0, t)/C_O^*$ is 0.01 for $E - E_O^\circ = -118\text{ mV}$ and 0.001 for $E - E_O^\circ = -177\text{ mV}$ according to the Nernst equation (Eq. 1). While the potential applied therefore does not need to be polarized much in the case of a reversible process for achieving zero surface concentration, the potential step required for quasi-reversible and, in particular, irreversible electrode reactions will be much larger. The appropriate potential value for a given process may be determined by means of cyclic voltammetry.

The disadvantage of the CA technique is that it is a “blind” technique, which is suitable for quantitative measurements only when it is combined with more direct techniques such as cyclic voltammetry. No direct information about intermediates

Figure 3. Chronoamperometric curve recorded for an $E_rC_iE_r$ mechanism: a) plot of current vs time, b) plot of time-normalized current ($i\sqrt{t}$) vs the logarithm of time, c) plot of number of electrons (n , see text) vs the logarithm of time, and d) plot of n vs logarithm of the dimensionless rate constant ($\lambda = k_1 t$).

can be found by CA, so it is generally of limited value for mechanistic studies. The recorded current usually depends only on the diffusion process of O to the electrode and the electron stoichiometry of the electrode process, represented by n . Almost all CA experiments lead to curves with similar shapes and only a closer examination of the curves will reveal if reliable kinetic information can be extracted. For instance, the i versus t curve for the E_rC_i mechanism (Eqs. 24 and 25) will be exactly the same as the curve for the corresponding E_iC_i mechanism. On the other hand, it will provide some information if the electron stoichiometry is dependent on the rate of a chemical step.

In Figure 3(a), the curve obtained in CA for the $E_rC_iE_r$ reaction mechanism (Eqs. 30–32) is depicted for $k_1 = 10 \text{ s}^{-1}$. A plot of $i\sqrt{t}$ versus $\log t$ as shown in Figure 3(b) can eliminate the time dependence of the current due to the growth of the diffusion layer. In the plot shown in Figure 3(c), the $i\sqrt{t}$ values are normalized by division with the constant $i\sqrt{t}$ value obtained at $t < 2 \text{ ms}$, where the influence of the follow-

Figure 3 (continued)

up reaction is negligible. Figure 3(c) can immediately be divided into three zones according to the apparent value of n ; I: $t < 2$ ms, where $n = 1$, II: $2 \text{ ms} < t < 322$ ms, where $1 < n < 2$, and III: $t > 322$ ms, where $n = 2$. If k_1 is larger than 10 s^{-1} , the three zones would be shifted to a shorter time. A general zone diagram for the $E_r C_i E_r$ reaction mechanism can be obtained by introduction of a dimensionless rate constant $\lambda = k_1 t$. This diagram with the three zones is shown in Figure 3(d), where zone I with $n = 1$ is found at $\lambda < 0.02$. In French, this zone is called “diffusion pure 1” or DP1. In zone II ($0.02 < k_1 t < 3.22$), n is controlled by the competition between kinetics and diffusion and it is called the “kinetic intermédiaire” or the KI zone. Finally, the third zone ($\lambda > 3.22$), denoted as “kinetic pure,” or KP, is completely controlled by the follow-up process and here $n = 2$. Actually, the limits between the different zones depend on the accuracy of the current measurements. In the above discussion, the uncertainty of the current was assumed to be 2 %, but if the precision is higher, the KI zone would be further expanded at the expense of the

two other zones. In that case, the kinetic window of the CA technique is widened and quantitative measurements relying on the crossing between the different zones will be easier to carry out.

A simple example illustrating how the determination of n in CA could be used in a mechanistic description is the reduction of benzyl chloride in aprotic media. Suppose the value of n in the KP zone is one, unless an acid, BH, is present; then n turns out to be 2. This could be explained by the mechanism proposed in Eqs. 40–42.

In the first step, the two-electron reduction of benzyl chloride would lead to the formation of chloride and the benzyl anion (Eq. 40). The latter species may either react as a nucleophile or base. If it reacts with the starting material, benzyl chloride, in an $\text{S}_{\text{N}}2$ reaction (Eq. 42), then the flux of O is halved; this explains why the overall electron consumption corresponds to one. In the presence of an acid, on the other hand, the benzyl anion is protonated and n becomes equal to two (Eq. 43).

CA can also be used for the study of reaction schemes involving equilibrium reactions that are established prior to the heterogeneous electron-transfer step. For instance, the equilibrium constant, K_{43} , for the palladium ligand-exchange reaction shown in Eq. 43, where the ligand dba (dibenzylideneacetone) is substituted with PPh_3 (triphenylphosphine), was determined by CA [4]. Both Pd complexes can be oxidized, with $\text{S-Pd}^\circ(\text{PPh}_3)_3$ being the easiest to oxidize.

Thermodynamically, the equilibrium is positioned on the left-hand side, but when $\text{S-Pd}^\circ(\text{PPh}_3)_3$ is oxidized at the electrode, it is shifted to the right. Interestingly, in cyclic voltammetry, a plateau-shaped rather than peak-shaped voltammogram is seen, because the diffusion layer of $\text{S-Pd}^\circ(\text{PPh}_3)_3$ grows in an unusual manner as the concentration of $\text{S-Pd}^\circ(\text{PPh}_3)_3$ is buffered through the above equilibrium process. Still, it is difficult to quantify K_{43} in cyclic voltammetry on the basis of the shapes of the voltammograms. In CA, on the other hand, the situation is easier, as the current depends only on the electron stoichiometry and the amount of the substrate present. The value of K_{43} can therefore be obtained simply by measuring the ratio of the currents pertaining to the oxidation of $\text{S-Pd}^\circ(\text{PPh}_3)_3$ and $\text{Pd}^\circ(\text{dba})(\text{PPh}_3)_2$. Both oxidation processes are two-electron processes and the application of a small step time results in the equilibrium becoming “frozen” during the experiment, making only the equilibrium concentrations available for the electrode reactions.

The use of CA in combination with other techniques has also lead to a general methodology for the determination of n and D for electrode processes. Whereas the current in the CA technique for ordinary micro-electrodes is proportional to $n\sqrt{D}$

(see Eq. 39), there are other functional relationships between n and D in other techniques, i.e. in steady-state voltammetry with an ultramicroelectrode (see Section 2.4), the plateau current, i_{ss} , is directly proportional to nD . Thus, a comparison of the responses from two different techniques will allow the isolation of n and D if the areas of the electrodes used in the experiments are accurately known. This is not always the case, and reference compounds such as ferrocene (fc) or $\text{Fe}(\text{CN})_6^{4-}$ with known n ($= 1$) and D values are therefore often introduced into the cell. The procedure suggested by Amatore and coworkers is outlined below [5]: A cell containing substances O and ferrocene in known concentrations is prepared; separate CA experiments are carried out on O and ferrocene with the use of a microelectrode. The normalized current ratio a_{CA}^* is calculated according to Eq. 44.

$$a_{\text{CA}}^* = \frac{n_{\text{O}}}{n_{\text{fc}}} \left[\frac{D_{\text{O}}}{D_{\text{fc}}} \right]^{1/2} = \left(\frac{i_{\text{O}}}{i_{\text{fc}}} \right) \left(\frac{C_{\text{fc}}^*}{C_{\text{O}}^*} \right) \quad (44)$$

The microelectrode is then replaced by an ultramicroelectrode, and steady-state voltammograms of O and ferrocene are recorded; this allows calculation of the ratio between the normalized plateau currents, a_{ss}^* (Eq. 45).

$$a_{\text{ss}}^* = \frac{n_{\text{O}}}{n_{\text{fc}}} \left[\frac{D_{\text{O}}}{D_{\text{fc}}} \right] = \left(\frac{i_{\text{pl, O}}}{i_{\text{pl, fc}}} \right) \left(\frac{C_{\text{fc}}^*}{C_{\text{O}}^*} \right) \quad (45)$$

The number of electrons, n_{O} , involved in the reduction of O and the diffusion coefficient D_{O} can now easily be obtained from Eqs. 46 and 47, respectively.

$$n_{\text{O}} = \frac{(a_{\text{CA}}^*)^2 n_{\text{fc}}}{a_{\text{ss}}^*} \quad (46)$$

$$D_{\text{O}} = \left(\frac{a_{\text{ss}}^*}{a_{\text{CA}}^*} \right)^2 D_{\text{fc}} \quad (47)$$

Interestingly, n_{O} and D_{O} can also be obtained from a single CA experiment if an ultramicroelectrode is used [6]. Following the potential step, planar diffusion will initially dominate, as the diffusion layer is smaller than the radius of the electrode. The current thus follows the usual Cottrell equation (Eq. 39). Later in the CA experiment, however, the diffusion layer grows larger than the radius of the ultramicroelectrode, and spherical diffusion will now dominate. This results in a time-independent current, given by Eq. 48 if the electrode is disc shaped, or Eq. 49 for microsphere geometry.

$$\text{Disc:} \quad i_{\text{ss, disc}} = 4rn_{\text{O}}FD_{\text{O}}C_{\text{O}}^* \quad (48)$$

$$\text{Microsphere:} \quad i_{\text{ss, sphere}} = n_{\text{O}}FAD_{\text{O}}C_{\text{O}}^*/r \quad (49)$$

Combination of Eq. 48 with Eq. 39 (see also Eq. 80 in Section 2.4) results in Eq. 50

for a disc electrode, where D_O can be obtained from the slope of a plot of $i(t)/i_{ss, disc}$ versus $t^{-1/2}$.

$$\text{Disc: } i(t)/i_{ss, disc} = \left(\frac{\pi^{1/2} r}{4D_O^{1/2}} \right) t^{-1/2} + 1 \quad (50)$$

Afterwards, n_O can be calculated from Eq. 48 for a disc electrode by insertion of the value for D_O .

2.2.2 Sampled-Current Voltammetry

If the potential applied in CA is not polarized sufficiently to fulfil the condition $C_O(0, t) = 0$, the current also depends on the heterogeneous electron-transfer kinetics. The Cottrell expression given in Eq. 39 should for a reversible process then be modified according to Eq. 51, where i_{cot} denotes the Cottrell current.

$$i = \frac{i_{cot}}{1 + \left(\frac{D_O}{D_R} \right)^{1/2} \exp \left(\frac{nF}{RT} (E - E_O^\circ) \right)} \quad (51)$$

In a sampled current voltammetry experiment, small potential steps are made progressively as shown in Figure 4(a) within the typical limits of $E_O^\circ + 200$ mV and $E_O^\circ - 200$ mV for a reversible process. The i versus E curve can be constructed (Figure 4(b)) with the following characteristics for the reversible process: the limiting current, i_l , obtained at $E - E_O^\circ < -118$ mV, is proportional to C_O^* , $E_{3/4} - E_{1/4} = -\frac{56.4}{n}$ mV (Tomeš criteria) and a plot of E versus $\log[(i_l - i)/i]$ has a slope of $\frac{59.2}{n}$ mV at 25 °C.

2.2.3 Double-Potential-Step Chronoamperometry

A double-potential-step chronoamperometry (DPSC) experiment consists of two CA experiments. The potential of the second step is normally adjusted so that the R molecules formed upon reduction of O in the first step is reoxidized to O in a diffusion-controlled process, but it might also be adjusted to other values with the purpose of detecting other species formed [7]. In contrast to the CA technique, DPSC is a reversal technique, where the intermediates/products formed during the first step are probed directly in the second step. In this sense, it corresponds to a pump/probe experiment in photochemistry. While CA, in general, provides little if any information about follow-up chemistry, DPSC is a very strong tool for distinguishing between different mechanisms such as for example E, EC_i, and DIM1. It is also a good tool for the determination of the relevant rate constants.

Traditionally, a DPSC experiment on O is carried out in the following manner: Initially, the potential E_i is held at a much more positive value than E_O° , so no re-

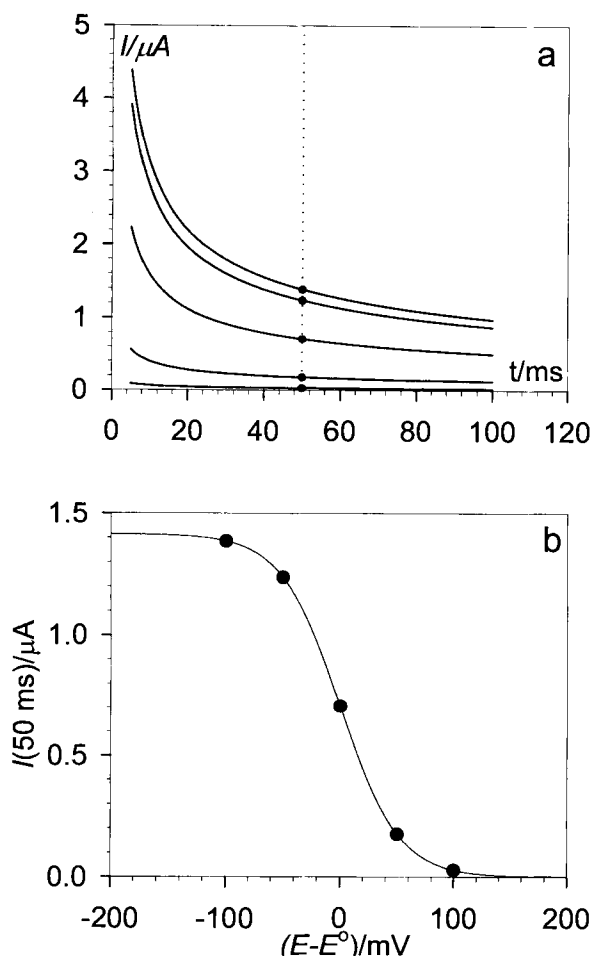

Figure 4. Sampled current voltammetry: a) Potential step experiments for E equal to $E_0^\circ + 100$ mV (lowest curve), $E_0^\circ + 50$ mV, E_0° , $E_0^\circ - 50$ mV, and $E_0^\circ - 100$ mV. b) The current recorded at 50 ms is plotted versus the step potential E as the sigmoid curve. The points shown in (a) are included in (b).

duction occurs. At $t = 0$, the potential is stepped abruptly to E_1 , a much more negative potential than E_0° ; this will generate R at a diffusion-controlled rate at the electrode surface for a period τ . At $t = \tau$ the potential is stepped to E_2 , which normally is equal to E_i , to reoxidize R to O. This potential value is maintained until $t = 2\tau$ and the current ratio $P = -\frac{i(2\tau)}{i(\tau)}$ can be evaluated. For simple reversible or

quasi-reversible heterogeneous electrode processes unaffected by kinetic follow-up reactions, P is equal to 0.293 for any value of τ and C_O^* . The reason why P is smaller than unity is that the R molecules formed at the electrode during the first step either diffuse towards the electrode surface or the bulk of the solution during the second step. In other words, only about 30 % of the generated R molecules are “recaptured” by the electrode.

Consider now an E_rC_i mechanism as shown in Eqs. 24 and 25, where, in a chemical step, R reacts further to the electroinactive species Y with a rate constant k . If this reaction proceeds on a timescale much smaller than τ , then all R is de-

Figure 5. Zone diagram for an E_rC_i mechanism based on DPSC measurements of the

current ratio $P = -\frac{i(2\tau)}{i(\tau)}$ vs the logarithm of the dimensionless rate constant, $k\tau$. The DP zone is for $k\tau < 0.018$, the KI zone for $0.018 < k\tau < 2.44$, and, finally, the KP zone for $k\tau > 2.44$. In the plot it is shown (dotted lines) how $\log k\tau_{0.5} = -0.393$ can be obtained from $P' = 0.5$.

pleted in the diffusion layer and thus $P = 0$. Should the chemical step, on the other hand, be so slow that it can be neglected, P is equal to 0.293, corresponding to a simple E_r mechanism. For the intermediate situation, where the timescale of the chemical reaction is comparable to τ , the value of P will be somewhere between 0 and 0.293. The above features are most conveniently illustrated by the construction of a zone diagram as shown in Figure 5, based on the dimensionless rate constant $\lambda = k\tau$. On the assumption that the precision of the current measurements is within 2 %, the DP zone appears for $\lambda < 0.018$ where the current response is totally unperturbed by the follow-up reaction. The KP zone, characterized by $P = 0$, is then found for $\lambda > 2.44$, and the intermediate zone KI, characterized by $0 < P < 0.293$, is observed for $0.018 < \lambda < 2.44$. From an experimental point of view, the ratio P can be varied simply by use of different step times τ in a series of experiments promoting the passage of the reaction system from one zone to another. It is difficult to accomplish the complete passage from $DP \rightarrow KI \rightarrow KP$, as it would require a variation in τ of a factor of 130 within the time window of the DPSC technique that normally ranges from 1 to 1000 ms. Fortunately, a shift between just two zones is usually sufficient for kinetic analysis; the rate constant may be extracted from a comparison between the experimental plot of P vs $\log \tau$ and the simulated curve shown in Figure 5.

The smallest first-order rate constant that can be measured in this manner from the $DP \rightarrow KI$ passage is $0.018/\tau_{\max} = 0.018 \text{ s}^{-1}$, assuming $\tau_{\max} = 1000 \text{ ms}$. Similarly, the maximum first-order rate constant that can be measured from the $KP \rightarrow KI$ passage is expected to be $2.44/\tau_{\min} = 2.4 \times 10^3 \text{ s}^{-1}$, with τ_{\min} equal to 1 ms.

For some applications, the P ratio is normalized by division by 0.293. This means that the normalized parameter $P' = P/0.293$ like P is zero in the KP zone for an E_rC_i mechanism, but one in the DP zone. A particular simple approach for the determination of rate constants by DPSC is based on the measurement of the step time $\tau_{0.5}$ at which P' is equal to 0.5 (i.e., $P = 0.1464$). For the E_rC_i mechanism, the equation $\log \lambda_{0.5} = \log(k\tau_{0.5}) = -0.393$ holds; this is illustrated by the dotted lines in Figure 5. Thus, the rate constant k can easily be calculated as $0.405/\tau_{0.5}$. Similar simple relationships have been obtained for other mechanisms, and they are included in Table 1.

Table 1. Equations for calculating rate constants for simple reaction mechanisms based on the reaction order approach for DPSC [137].

Mechanism	Rate constant, k	$\frac{\partial \log \tau_{0.5}}{\partial \log C_O^*}$
$E_r C_i$	$0.405/\tau_{0.5}$	0
DISP ($E_r C_i E_h$)	$0.272/\tau_{0.5}$	0
DIM1	$0.830/(\tau_{0.5} C_O^*)$	-1
DIM2	$0.678/(\tau_{0.5} C_O^*)$	-1

From the definition of $\lambda_{0.5}$, it follows that $\tau_{0.5}$ is inversely proportional to the rate constant of the chemical reaction. The influence of substrate concentration, proton concentration (pH), and temperature on the reaction rate can therefore be deduced simply from the variation in $\tau_{0.5}^{-1}$. For example, the reaction order of the substrate can be determined as $-\partial \log \tau_{0.5} / \partial \log C_O^*$. Likewise, apparent activation energies, E_a , may be obtained from plots of $\tau_{0.5}^{-1}$ against the inverse temperature (T^{-1}), since the slope is equal to $-E_a/R$ [8]. Kinetic isotope effects can also easily be quantified as $\frac{k_H}{k_D} = \frac{\tau_{0.5,D}}{\tau_{0.5,H}}$ [9].

A sophisticated use of DPSC has been that of the selection of step potentials for the detection of various intermediates. One such example was provided by Amatore *et al.*, showing that the formation $Cr_2(CO)_{10}^{2-}$ on a short timescale upon reduction of $Cr(CO)_6$ was by an $E_r C_i C_2$ mechanism involving the dimerization of two $Cr(CO)_5^{-\bullet}$ molecules [7]. This mechanism differs from the one observed on a longer timescale, where $Cr(CO)_5^{2-}$, formed in a two-electron reduction of $Cr(CO)_6$, can react with $Cr(CO)_6$ to yield $Cr_2(CO)_{10}^{2-}$ and CO.

The development of ultramicroelectrodes with characteristic physical dimensions below 25 μm has allowed the implementation of faster transients in recent years, as discussed in Section 2.4. For CA and DPSC this means that a smaller step time τ can be employed, while there is no advantage to a larger τ . Rather, steady-state currents are attained here, owing to the contribution from spherical diffusion for the small electrodes. However, by combination of the use of ultramicroelectrodes and microelectrodes, the useful time window of the techniques is widened considerably. Compared to scanning techniques such as linear sweep voltammetry and cyclic voltammetry, described in the following, the step techniques have the advantage that the responses are independent of heterogeneous kinetics if the potential is properly adjusted. The result is that fewer parameters need to be adjusted for the determination of rate constants.

2.3 Linear Sweep Voltammetry and Cyclic Voltammetry

In linear sweep voltammetry (LSV), the potential of the working electrode is changed linearly from an initial to a final potential in a single scan. If the potential

Figure 6. The potential vs time plot for cyclic voltammetry. For linear sweep voltammetry only the first linear ramp is used.

limits are adjusted so that the standard potential of the substrate O is positioned between the two limits, a reduction process will take place according to Eq. 2. In cyclic voltammetry (CV), two scans are applied, in which the potential is changed linearly from an initial potential to a switch potential and then back to the initial potential. The characteristic E vs t plot for this technique is shown in Figure 6. A linear sweep voltammogram or a cyclic voltammogram is a plot of the measured current versus the applied potential, as illustrated in Figure 7 for three specific cases, the reversible, quasi-reversible, and irreversible processes. These cases will be discussed in detail later.

In CV, substrates are generally activated during the first scan by electron transfer and the reverse scan is then used to detect the activated substrates. The formation of other electrochemically active intermediates or products can also be revealed by these scans or possibly by the performance of multiscans. The CV technique is, like DPSC, similar to the pump/probe experiment known from photochemistry, but in CV, unique knowledge about the thermodynamic properties of the intermediates

Figure 7. Simulated cyclic voltammograms pertaining to $O + e \rightleftharpoons R$ for three different values of the dimensionless heterogeneous rate constant

$\psi = \frac{\left(\frac{D_O}{D_R}\right)^{1/2} k^\circ}{[D_O \pi \nu (nF/RT)]^{1/2}}$: a) solid line, $\psi = 30$, b) dotted line, $\psi = 0.3$ and c) dashed line, $\psi = 0.03$. If $D_O = D_R = 10^{-5} \text{ cm}^2 \text{ s}^{-1}$, $\nu = 1 \text{ V s}^{-1}$ and $T = 25^\circ \text{C}$, then a) $k^\circ = 1 \text{ cm s}^{-1}$, b) $k^\circ = 0.01 \text{ cm s}^{-1}$ and c) $k^\circ = 0.001 \text{ cm s}^{-1}$. Note that the latter case with $k^\circ = 0.001 \text{ cm s}^{-1}$ is not strictly irreversible according to the definitions given for k° below.

can be obtained from the measured potentials. The time parameter in the experiment is the sweep rate, v , that is, the rate at which the potential is changed with time. The introduction of ultramicroelectrodes has extended the upper limit of sweep rates in CV to 1 MV s^{-1} , allowing the detection and characterization of intermediates with a lifetime as small as $1 \mu\text{s}$.

If O is the only species initially present in the electrochemical cell and there is no homogeneous kinetics, migration and convection, so the mass transport occurs by diffusion, the LSV experiment can be characterized mathematically by the following equations.

$$\text{Fick's second law:} \quad \frac{\partial C_{\text{O}}(x, t)}{\partial t} = D_{\text{O}} \frac{\partial^2 C_{\text{O}}(x, t)}{\partial x^2} \quad (52)$$

$$\text{Initially:} \quad t = 0, \quad C_{\text{O}}(x, 0) = C_{\text{O}}^*; \quad C_{\text{R}}(x, 0) = 0 \quad (53)$$

$$\text{Far from the electrode:} \quad x \rightarrow \infty, \quad C_{\text{O}}(x, t) = C_{\text{O}}^*; \quad C_{\text{R}}(x, t) = 0 \quad (54)$$

$$\text{Electrode surface:} \quad x = 0,$$

$$\text{Reversible:} \quad \frac{C_{\text{O}}(0, t)}{C_{\text{R}}(0, t)} = \exp\left(\frac{nF(E_i - vt - E_{\text{O}}^{\circ})}{RT}\right) \quad (55)$$

$$\begin{aligned} \text{Quasi-reversible:} \quad & D_{\text{O}} \left(\frac{\partial C_{\text{O}}(x, t)}{\partial x} \right)_{x=0} \\ &= k^{\circ} \left[\exp\left(\frac{-\alpha nF(E_i - vt - E_{\text{O}}^{\circ})}{RT}\right) C_{\text{O}}(0, t) \right. \\ &\quad \left. - \exp\left(\frac{(1 - \alpha)nF(E_i - vt - E_{\text{O}}^{\circ})}{RT}\right) C_{\text{R}}(0, t) \right] \end{aligned} \quad (56)$$

$$\begin{aligned} \text{Irreversible:} \quad & D_{\text{O}} \left(\frac{\partial C_{\text{O}}(x, t)}{\partial x} \right)_{x=0} \\ &= k^{\circ} \exp\left(\frac{-\alpha nF(E_i - vt - E_{\text{O}}^{\circ})}{RT}\right) C_{\text{O}}(0, t) \end{aligned} \quad (57)$$

$$\text{Fick's first law:} \quad i(t) = nFAD_{\text{O}} \left(\frac{\partial C_{\text{O}}(x, t)}{\partial x} \right)_{x=0} = -nFAD_{\text{R}} \left(\frac{\partial C_{\text{R}}(x, t)}{\partial x} \right)_{x=0} \quad (58)$$

Note that in the description of the conditions at the electrode surface, the exact nature of the electron-transfer process should be taken into account, that is, if it is under thermodynamic control as in the reversible case (Eq. 55) or kinetically controlled as in the quasi-reversible (Eq. 56) and irreversible cases (Eq. 57). This is contrary to the situation in a CA and DPSC experiment where the potential is usually stepped to a potential value where the surface concentration of O becomes

zero and the process thus becomes diffusion-controlled, regardless of the value of the standard heterogeneous rate constant.

For the LSV and CV techniques, the concept of reversibility/irreversibility is therefore very important. Electrochemists are responsible for some confusion about the term irreversible, since a reaction may be electrochemically irreversible, yet chemically reversible. In electrochemistry, the term irreversible is used in a double sense, to describe effects from both homogeneous and heterogeneous reactions. In both cases, the irreversible situation arises when deviations from the Nernst equation can be seen as fast changes in the electrode potential, E , are attempted and the apparent heterogeneous rate constants, k_{app} , for the O/R redox couple is relatively small. The heterogeneous rate constant can be split into two parts: a constant factor in terms of the standard rate constant, k° , and an exponential function of the overpotential ($E - E^\circ$), as expressed in Eq. 59, where only the reductive process is considered (see also Eq. 5).

$$k_{\text{app}} = k^\circ \exp \left[\frac{-\alpha n F}{RT} (E - E^\circ) \right] \quad (59)$$

Several factors, such as large structural differences between O and R or hindered access for the redox center approaching the electrode surface, can lower k° . The apparent heterogeneous rate constant might also be diminished by the potential factor when the overpotential, $E - E^\circ$, is positive, that is, $E > E^\circ$, which can be the case when the heterogeneous reaction is followed by a very fast chemical reaction. To keep these situations separate, we will first look at charge-transfer reactions where no preceding or following chemical reactions are present, and afterwards we will consider the effect of including chemical reactions.

2.3.1 Charge-Transfer Reactions

Charge-transfer reactions (Eq. 2) occurring at the electrode surface are conveniently classified as Nernstian (reversible), quasi-reversible, or irreversible, depending on the standard heterogeneous rate constant, k° . If the rate constant is large, the surface concentrations will be adjusted to the electrode potential as expressed in the Nernst equation (Eq. 1). A practical definition of reversibility is conditions where the ratio of surface concentrations of O and R is constantly in accordance with the Nernst equation. Redox reactions are quasi-reversible/irreversible when deviations from the Nernst equation can be detected. The irreversible case is characterized by the complete lack of a reverse reaction, while for the quasi-reversible case, the reverse reaction has to be considered although the electron-transfer kinetics is slow. The assignment of a given redox system to either of the three cases depends on the electrochemical technique used and the timescale of the experiment. In LSV and CV, the timescale is expressed by $\frac{RT}{Fv}$, which roughly corresponds to the time needed to scan the potential from E° to the peak potential for a reversible process.

Matsuda and Ayabe suggest the following zone boundaries for the heterogeneous kinetics when $D_O = D_R$, $\alpha = 0.5$, $T = 25^\circ\text{C}$, and ν is given in V/s [10]:

$$\text{Reversible: } k^\circ \geq 0.3\sqrt{n\nu} \text{ cm/s}$$

$$\text{Quasi-reversible: } 0.3\sqrt{n\nu} \text{ cm/s} \geq k^\circ \geq 2 \times 10^{-5}\sqrt{n\nu} \text{ cm/s}$$

$$\text{Irreversible: } k^\circ \leq 2 \times 10^{-5}\sqrt{n\nu} \text{ cm/s}$$

Thus, at high $k^\circ/\nu^{1/2}$ ratios (fast heterogeneous kinetics or low sweep rate), the cyclic voltammogram will appear reversible. Increase of the sweep rate will gradually transform it into a quasi-reversible and irreversible voltammogram. In the kV/s range of sweep rates, even the redox pair with the largest heterogeneous rate constants k° of 10 cm/s will appear quasi-reversible.

2.3.2 Nernstian Charge Transfer

The cyclic voltammogram for a Nernstian or reversible charge-transfer process, as shown in Figure 7(a), is characterized by the presence of peaks on both the forward and reverse scans. The peak shape is due to the fact that the current at first increases exponentially because of the increasing overpotential as predicted by the current-potential equation (Eq. 8), but later the mass-transport process in terms of diffusion manifests itself through $C_O(0, t)$. At sufficiently negative potentials on the forward scan and at sufficiently positive potentials on the reverse scan, compared to E° , the current becomes limited by the diffusion process and will thus be proportional to $t^{-1/2}$. In the intermediate region of mixed control, the peaks appear at positions that are independent of sweep rate and substrate concentration. The peak potential for the forward scan E_p is equal to $E_O^\circ - 1.109RT/nF = E_O^\circ - 28 \text{ mV}$ for $n = 1$ and $T = 25^\circ\text{C}$, and the separation between the oxidation and reduction peak potentials, ΔE_p , is 57 mV. (The exact value is slightly dependent on the chosen switch potential). Moreover, the half-peak width, $E_p - E_{p/2}$, is equal to -56.5 mV . The peak current is proportional to the substrate concentration and $\nu^{1/2}$, while the peak current ratio, $-i_{p, \text{ox}}/i_{p, \text{red}}$, is unity, and independent of ν [1]. Potentials of thermodynamic significance can, strictly speaking, only be obtained from reversible voltammograms.

2.3.3 Quasi-Reversible and Irreversible Charge Transfer

If k° is relatively small, the ratio of the surface concentrations, $C_O(0, t)/C_R(0, t)$ deviates from the value provided by the Nernst equation. For a reduction process this means that $C_O(0, t)$ would be higher and $C_R(0, t)$ smaller at a given value of E than predicted from Eq. 1. Expressed differently, a larger overpotential is required when k° is small if a current similar to that in the reversible case is to be obtained. The result is that the voltammograms will be displaced to lower potentials, as

Table 2. The difference between the oxidative and reductive peak potentials, ΔE_p , as a function

of the dimensionless heterogeneous rate constant, $\psi = \frac{\left(\frac{D_O}{D_R}\right)^{\alpha/2} k^\circ}{[D_O \pi \nu (nF/RT)]^{1/2}}$. The ΔE_p values were obtained from digital simulation with $D_O = D_R = 10^{-5} \text{ cm}^2 \text{ s}^{-1}$, $T = 25^\circ\text{C}$, $n = 1$, and switch potential, $E_\lambda = E_O^\circ - 400 \text{ mV}$.

ψ	$\Delta E_p/\text{mV}$	ψ	$\Delta E_p/\text{mV}$
20	58.8	0.1	216
10	60.1	0.05	284
5	62.7	0.02	378
2	70.3	0.01	450
1	82.4	0.005	520
0.5	105	0.002	620
0.2	157	0.001	690

shown in Figure 7. These are the quasi-reversible (curve b) and irreversible (curve c) cases.

For quasi-reversible charge transfer, E_p and ΔE_p are functions of ν , k° , and α . Moreover, i_p is not proportional to $\nu^{1/2}$ as found for reversible charge transfer. The cyclic voltammograms are described by the dimensionless parameters α and ψ defined in Eq. 60.

$$\psi = \frac{\left(\frac{D_O}{D_R}\right)^{\alpha/2} k^\circ}{[D_O \pi \nu (nF/RT)]^{1/2}} \quad (60)$$

The peak-potential difference ΔE_p depends mainly on the kinetic parameter ψ , as illustrated in Table 2. By measurement of ΔE_p as a function of ν for a given system, k° can be estimated. However, great care should be exerted to ensure that uncompensated resistance does not contribute to the value of ΔE_p , since this would hamper the procedure. Clearly, the use of ultramicroelectrodes can be recommended for this kind of measurements, as the ohmic drop is much smaller here compared to microelectrodes of normal size. This is particularly true when high sweep rates are required for determining large values of k° (see Section 2.4).

If k° becomes even smaller, a new limiting form is attained, that is, the irreversible case, where the backward reaction is negligible at the potentials where the forward process takes place. For the totally irreversible wave, i_p is proportional to the bulk concentration C_O^* and $\nu^{1/2}$, as was the case for the reversible charge-transfer case even though the absolute current here was larger. However, E_p is shifted in a negative direction by $30/\alpha n \text{ mV}$ for each decade change in ν , and the wave is broad with a half-peak width, $E_p - E_{p/2}$, of $-47.7/\alpha n \text{ mV}$, compared to the -56.5 mV for the reversible case. In this situation, there is no straightforward access to either k° nor E_O° , unless other techniques such as convolution are employed [11].

2.3.4 Ohmic Drop

The potential applied to the working electrode is always measured relative to a reference electrode. In organic solvents, a substantial potential drop might be included in the measurements due to the non-zero resistance, R , between the working electrode and the reference electrode. The real potential felt at the working electrode is therefore different from the applied potential. The potential drop, often referred to as the ohmic drop or iR drop, is proportional to the current, i , at the working electrode. As a result, the ohmic drop can be substantial if high sweep rates are employed for the study of high substrate concentrations at large electrodes in resistive media. For instance, in *N,N*-dimethylformamide or acetonitrile at microelectrodes (diameter ≈ 1 mm), with substrate concentrations in the millimolar range, the ohmic drop is important for sweep rates higher than 1 V s^{-1} . The ohmic drop may partly be compensated by positive feedback systems incorporated in the potentiostats, but even then this does not work if sweep rates higher than 1000 V s^{-1} are applied at normal-sized microelectrodes. For ultramicroelectrodes, the ohmic drop is less important and can be neglected for $v < 1000 \text{ V s}^{-1}$.

2.3.5 Coupled Chemical Reactions

So far we have assumed that the redox couple in the charge-transfer reaction is stable towards chemical reactions within the timescale of the LSV or CV experiments. However, in many cases the charge transfer at the electrode to or from a molecule will result in the formation of a radical species (odd-electron) or another reactive species which will react either at the electrode or in homogeneous solution to form more stable products. If R undergoes a fast homogeneous reaction, then more O has to be converted to R at the electrode surface to maintain the surface concentration ratio as required by the Nernst equation (Eq. 1). A fast follow-up reaction will therefore cause a reduction current at less extreme potentials than if no chemical reaction takes place. This is illustrated in Figure 8, where the cyclic voltammograms pertaining to an E_rC_i and an E_r mechanism are shown. The shift in potential for the E_rC_i mechanism renders the overpotential, $E - E_O^\circ$, positive ($E > E_O^\circ$); this implies that the apparent heterogeneous rate constant is diminished by the potential factor (see Eq. 59). Moreover, the shift in potential will depend on the type of follow-up reaction. For a first-order follow-up reaction, the peak potential will be shifted according to Eq. 61, while for a second-order process Eq. 62 applies.

$$\text{First order:} \quad \partial E_p / \partial \log(k/v) = 29.6 \text{ mV/decade} \quad \text{at } 25^\circ\text{C} \quad (61)$$

$$\text{Second order:} \quad \partial E_p / \partial \log(kC_O^*/v) = 19.7 \text{ mV/decade} \quad \text{at } 25^\circ\text{C} \quad (62)$$

It should be emphasized that these slopes are only valid when $n = 1$ and the wave is purely kinetic, that is, the chemical reaction is so fast that a stationary state is established by mutual compensation of the chemical reaction of the intermediate

Figure 8. Simulated cyclic voltammograms for $E_r C_i$ mechanism: a) without follow-up reaction of R ($k_1 = 0 \text{ s}^{-1}$), and b) with a fast follow-up reaction ($k_1/v = 5 \times 10^{12} \text{ V}^{-1}$).

and the diffusion processes. Increasing the sweep rate will make the voltammogram appear reversible, and the pure diffusion zone is then attained.

Very thorough theoretical analyses of the theoretical LSV slopes, $\partial E_p / \partial \log v$ and $\partial E_p / \partial \log C_O^*$, for various reaction mechanisms were carried out by Nicholson and Shain [12, 13] and Savéant *et al.* [14–17]. These slopes are very useful in the elucidation of reaction mechanisms. By adaptation of the approach proposed by Parker [18], it is possible to develop simple general equations that directly relate the LSV slopes to the kinetic rate law of the process of interest. The rate law is assumed to be of the general type

$$\text{Rate} = k' C_O^o C_R^r C_I^i C_X^x \quad (63)$$

where the subscript O refers to the substrate, R is the primary intermediate, I is a secondary intermediate that may be formed during the process, and X is an additional reactant. The superscripts o, r, i, and x are the reaction orders in the participating species. The LSV slopes for mechanisms corresponding to the above rate law can be predicted directly from Eqs. 64 to 66.

$$\partial E_p / \partial \log v = \frac{-2.3RT}{nF(1+r)} \quad (64)$$

$$\partial E_p / \partial \log C_O^* = \frac{2.3RT(o+r+i-1)}{nF(1+r)} \quad (65)$$

$$\partial E_p / \partial \log C_X^* = \frac{2.3RTx}{nF(1+r)} \quad (66)$$

In Table 3, the LSV slopes for some of the most common mechanisms are listed.

As an illustrative example of the influence of homogeneous reactions on the cyclic voltammetric behavior, the oxidation of an anion R^- to the corresponding short-

^a*S*₁, *S*₂, and *S*₃ refer to $dE_p/d \log v$, $dE_p/d \log C_O^*$, and $dE_p/d \log C_X^*$, respectively, and are expressed in units of $(\ln 10)RT/nF$. The signs of *S*₁, *S*₂, and *S*₃ change if oxidation processes are considered.

^bTable 3 is taken from Ref. [18] with slight modifications.

lived radical R^* , followed by dimerization will be treated. The DIM1 mechanism is shown in Eqs. 67–68.

Transient radicals generated directly at the electrode by reduction or oxidation of a precursor will be present adjacent to the electrode in a thin reaction layer that is much smaller than the diffusion layer. Therefore, the concentration of the radical will be of the same order as the precursor concentration and second-order reactions become likely. This is contrary to most common radical reactions involving homogeneous approaches where the steady-state concentration of the radical is very low, because of slow rate-controlling formation and fast follow-up reactions. For the DIM1 mechanism $\partial E_p / \partial \log v = 19.7$ mV and $\partial E_p / \partial \log C_{R^-}^* = -19.7$ mV in the kinetic zone, noting that Eq. 67 is an oxidation process. The rate constant for the dimerization of the radical, k_{dim} , can often be estimated or assumed to be within one or two orders of magnitude from the diffusion limit. On this basis, it is possible to correct the measured totally irreversible oxidation potentials to standard potentials by Eq. 69.

$$E^\circ = E_p^{\text{ox}} + 0.0197 \log \left(\frac{k_{\text{dim}} C_{\text{R}^-}^*}{58.4\nu} \right) - 0.0232 \text{ V} \quad \text{at } 25^\circ\text{C} \quad (69)$$

If $C_{\text{R}^-}^*$ is 1 mM and ν is 0.1 Vs⁻¹, E° will be at a potential 60 mV higher than the observed irreversible oxidation potential, E_p^{ox} , on the assumption that k_{dim} is equal to 10⁸ M⁻¹ s⁻¹. For many solvents, the diffusion-controlled rate constant k_d is close to 10¹⁰ M⁻¹ s⁻¹, so the difference between E° and E_p^{ox} can at most be 100 mV. Recent examples where this procedure have been applied can be found in Refs. [19, 141]. Often the correction procedure is used in combination with fast cyclic voltammetry at ultramicroelectrodes when the voltammogram appears totally irreversible at the highest possible sweep rate, ν_{max} . Under these circumstances, the lower limit for k_{dim} can be estimated from Eq. 70.

$$k_{\text{dim}} > \frac{31.1\nu_{\text{max}}}{C_{\text{R}^-}^*} \text{ M}^{-1} \text{ s}^{-1} \quad \text{at } 25^\circ\text{C} \quad (70)$$

If $C_{\text{R}^-}^*$ is 1 mM and the maximum sweep rate applicable experimentally is, for example, 100 kV s⁻¹, then k_{dim} is at minimum $3 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, which narrows the range of k_{dim} to 3×10^9 to $10^{10} \text{ M}^{-1} \text{ s}^{-1}$ (i.e., k_d). With k_{dim} known within such a narrow range, E° can be estimated rather precisely by Eq. 69, if E_p^{ox} is measured accurately at low sweep rate at a normal microelectrode.

2.3.6 Mixed Charge Transfer and Kinetic Control

In the preceding chapter, the charge transfer was assumed to be so fast that it was Nernstian. However, this condition cannot always be fulfilled, either because the charge transfer is intrinsically slow (i.e., k° is small), or because the follow-up reaction causes the voltammetric wave to shift, thereby lowering the apparent heterogeneous rate constant k_{app} by the potential factor (Eq. 59). Let us consider once more the DIM1 (EC₂) mechanism, but now open for the possibility that the heterogeneous step is not necessarily reversible. It is then convenient to define two dimensionless parameters related to k° and k_{dim} :

$$A = \frac{k^\circ}{(D_O\nu)^{1/2}} \left(\frac{RT}{nF} \right)^{1/2} \quad (71)$$

$$\lambda = \frac{k_{\text{dim}} C_O^*}{\nu} \left(\frac{RT}{nF} \right) \quad (72)$$

The general behavior expected in LSV may then be computed by digital simulations [20] and the results can be conveniently visualized in a zone diagram as shown in Figure 9. For $\log \lambda < -1$, the dimerization reaction has no effect whatsoever, and the cyclic voltammetric behavior pertains to the reversible, quasi-reversible (QR), or totally irreversible charge transfer (IR), depending on the value of A . For very large

Figure 9. Zone diagram for a DIM1 (EC₂) mechanism, where the parameters λ and A are defined in the text.

values of A ($\log A > 2$) the charge transfer is always Nernstian and the wave is influenced by the follow-up reaction going from the pure diffusion zone, DP, over an intermediate region, KO, and further to the kinetically controlled zone, KP, for a large value of λ . The effects of joint electron transfer and chemical irreversibility are mainly manifested in zone KG.

The reaction-order approach and zone diagrams are very useful, as they often provide the necessary information from which a reaction mechanism can be proposed. Therefore, the first step in the elucidation of a reaction mechanism using LSV is usually the measurement of the diagnostic criteria, i.e. the peak potential and half-peak width as a function of sweep rate and concentrations of the reactants involved. Once a working scheme is set up, all the information available in the cyclic voltammograms should be considered, not just the peak potentials and peak widths, to either confirm or modify the proposed mechanism. In practice, this is done by comparison of experimental cyclic voltammograms with digitally simulated voltammograms. In recent years many simulation programs have become commercially available, and voltammograms for even rather complex mechanisms can be calculated straightforwardly. An example of this approach concerns the electrochemical reduction of 3-chloroacetophenone (AcCl) in aprotic solvents [21]. In cyclic voltammetry, a one-electron quasi-reversible system is seen at high sweep rates, showing that the reduction process leads to the formation of the radical anion in the first step. At lower sweep rates, the wave becomes irreversible due to follow-up reactions and a second peak pertaining to one of the products formed, acetophenone (AcH), appears at lower, that is, more negative potentials. This could be confirmed from a comparison with an authentic sample of AcH. The results point towards the presence of a cleavage reaction, where the carbon–chlorine bond in the radical anion of 3-chloroacetophenone is fragmented. However, measurement of the LSV slopes $\left(\frac{\partial E_p}{\partial \log v} \approx -19.7 \text{ mV} \text{ and } \frac{\partial E_p}{\partial \log C_{\text{AcCl}}^*} \approx +19.7 \text{ mV} \right)$ for similar acetophenone systems reveals that the radical anion is also involved in a dimeriza-

tion reaction (DIM1). The following reaction scheme (Eqs. 73–79) was proposed.

This scheme describes the competition between, on one hand, the dimerization process (Eq. 74) and, on the other hand, the cleavage reaction (Eq. 75) of the radical anion, followed by fast hydrogen abstraction (Eq. 76) from the solvent SH (forming AcH) and reduction (Eq. 77) of the thus generated solvent radical. The second wave observed in the voltammogram is attributed to reduction (Eq. 78) of the generated acetophenone, the radical anion of which may reduce the remaining AcCl in a homogeneous reaction (Eq. 79). We have omitted the dimerization reaction of $\text{AcH}^{\bullet-}$ and the cross reaction between $\text{AcCl}^{\bullet-}$ and $\text{AcH}^{\bullet-}$ from the above scheme for the sake of simplicity.

Figure 10 shows a comparison of the simulated and experimental cyclic voltammograms; it encompasses the waves of both the starting compound, 3-chloroacetophenone, and the acetophenone formed during the scan. While the first wave is described well theoretically, the second wave of acetophenone deviates somewhat. The fit to the second wave may be improved by introduction of new processes involving the radical anion of acetophenone besides the dimerization and cross reactions. However, since reproducible values of k_{cl} and $2k_{\text{dim}}$ could be obtained by optimization of the fit to the first cyclic voltammetric wave for the different substrate concentrations and sweep rates employed, these reactions were not considered in greater detail.

2.4 Ultra microelectrodes

Since the mid-eighties, ultramicroelectrodes (UMEs) have been developed for many different applications. At an early stage, they were employed in biological and medical research where, for example, small electrodes were implanted in rat brains. The main difference between microelectrodes and UMEs is the mode of diffusion that shifts from planar to spherical, depending on the exact thickness of the diffusion layer. As long as the diffusion layer is smaller than the dimension of the electrode, the diffusion will also be planar for an UME. UMEs could be defined as

Figure 10. Cyclic voltammogram of 3-chloroacetophenone at a concentration of 2 mM, obtained at a glassy carbon electrode in THF/0.3 M Bu₄NBF₄ at a sweep rate of 0.2 V s⁻¹. The potential *E* is measured against fc⁺/fc. The simulated curve (O) is obtained with $k_c = 0.6 \text{ s}^{-1}$ and $2k_{\text{dim}} = 2 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$. Taken from H. Jensen and K. Daasbjerg, *Acta Chem. Scand.* 52:1151 (1998) [21].

electrodes where spherical diffusion dominates after 1 s in a CA experiment. Since the Cottrell equation given in Eq. 39 is valid only for planar diffusion, an extra term should be added to incorporate the contribution from spherical diffusion as stated in Eq. 80, where r is the radius of a microsphere electrode.

$$i = nFAD_0C_O^* \left[\frac{1}{(\pi D_0 t)^{1/2}} + \frac{1}{r} \right] \quad (80)$$

The second term in Eq. 80 that is proportional to r^{-1} describes the contribution from spherical diffusion; when it is 10 times larger than the planar diffusion term [i.e., $(\pi D_0 t)^{-1/2}$] after 1 s, this would lead to a definition of UMEs as stated in Eq. 81.

$$\left(\frac{r}{\pi^{1/2} D_0^{1/2}} \right) < 0.1 \quad (81)$$

In most cases, D_O is about $10^{-5} \text{ cm}^2 \text{ s}^{-1}$, and it then follows that the characteristic radius of an UME is smaller than $6 \mu\text{m}$. However, it is important to notice that D_O is sometimes appreciably smaller than $10^{-5} \text{ cm}^2 \text{ s}^{-1}$ if O is a very large molecule, or, more likely, if a viscous or glass-like medium is used; planar diffusion would then prevail even at a radius of $6 \mu\text{m}$. Note also that a microelectrode with a radius of $100 \mu\text{m}$ experiences a substantial contribution from spherical diffusion. If the geometry of the electrode differs from the simple disk or microsphere shape, the definition is less clear. In general, the characteristic behavior of a UME is observed if at least one of the dimensions is in the micrometer range. For instance, a band electrode with a width of less than $10 \mu\text{m}$ behaves as an UME even if it is several mm long.

Electrodes can be divided into four categories according to their characteristic dimensions: 1) Macroelectrodes, such as parallel plates, 2) Microelectrodes, 3) Ultramicroelectrodes, and 4) Nanoelectrodes. The four types of electrodes are illustrated in Figure 11 together with their characteristic electrical properties important for their applicability: resistance, R , double-layer capacitance, C_{dl} , and current, i .

The cell time constant, $\tau_{\text{cell}} = RC_{dl}$ expresses the ability of the cell to respond to fast changes in the electrode potential. Part of the current observed initially in a CA experiment in which the potential is changed suddenly is used to charge the double-layer capacitor and is called the capacitive current, i_c . Because this charging process passes the resistance in the cell, the current response will be the same as for a RC circuit, that is, an exponential function (Eq. 82).

$$i_c = \frac{\Delta E}{R} \exp\left(\frac{-t}{RC_{dl}}\right) \quad (82)$$

Thus, i_c decreases to zero with time and is diminished by more than 90 % when $t > 2.3RC_{dl}$. The cell time constant is a very important parameter for evaluation of the time elapsed until i_c has become insignificant compared to the faradaic current component pertaining to the electrode processes, i_f . For the LSV or CV techniques, i_c has two components, as shown in Eq. 83, since the potential is changed constantly throughout the experiment.

$$i_c = \left\{ \frac{E_i}{R} - vC_{dl} \right\} \exp\left(\frac{-t}{RC_{dl}}\right) + vC_{dl} = \left\{ \frac{E_i}{R} - vC_{dl} \right\} \exp\left(\frac{-(E - E_i)}{vRC_{dl}}\right) + vC_{dl} \quad (83)$$

There is a transient term at the beginning of the scan, with E_i denoting the initial potential applied prior to the potential sweep, and a nontransient or constant term, vC_{dl} . When the direction of the scan is reversed in CV, another transient contribution appears and the nontransient component of i_c changes sign. At high sweep rates it is difficult to separate the i_f component from i_c by use of subtraction procedures. Usually the contribution from the transient part is only acceptable within the first 100 mV of the potential scan, which leads to the expression shown in Eq. 84 for the maximum applicable sweep rate, v_{max} .

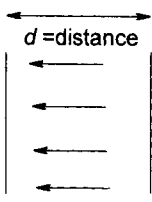

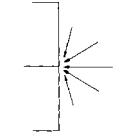

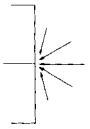

Electrode type	R	C_{dl}	i	iR	RC_{dl}
Macroelectrodes  $d = \text{distance}$ $A = \text{area}$	$\propto d/A$	$\propto A$	$\propto A$	$\propto d$	$\propto d$
Microelectrodes  $r = \text{radius}$	$\propto r^{-1}$	$\propto r^2$	$\propto r^2$	$\propto r$	$\propto r$
Ultramicroelectrodes  $r = \text{radius}$	Spherical dif. $\propto r^{-1}$	$\propto r^2$	$\propto r$	const	$\propto r$
	Planar dif. $\propto r^{-1}$	$\propto r^2$	$\propto r^2$	$\propto r$	$\propto r$
Nanoelectrodes 					

Figure 11. Electrochemical characteristics of four different types of electrodes. The expressions for the electrical properties of nanoelectrodes are complex and therefore not included.

Figure 12. Simulated cyclic voltammograms for 10- μm diameter hemi-spherical UME with $\alpha = 0.5$, $k^\circ = 10000 \text{ cm s}^{-1}$, $T = 25^\circ\text{C}$, $n = 1$, $R = 30 \text{ k}\Omega$, $C_{\text{dl}} = 20 \text{ pF}$, a) $\nu = 0.020 \text{ V s}^{-1}$, b) $\nu = 1.0 \text{ V s}^{-1}$, c) $\nu = 10^3 \text{ V s}^{-1}$, and d) $\nu = 10^6 \text{ V s}^{-1}$. The inset shows the effect of the time constant at the beginning of the scan for curve (c). Note that the current has been normalized with $\sqrt{\nu}$ and that for curve (a) the current has been divided by four.

$$\nu_{\text{max}} = \frac{4.3 \times 10^{-2}}{RC_{\text{dl}}} = \frac{4.3 \times 10^{-2}}{\tau_{\text{cell}}} \quad (\text{in V s}^{-1}) \quad (84)$$

For most electrode configurations, C_{dl} is proportional to r^2 because capacitance is a surface-related property, whereas the resistance in a cell containing a disk or hemisphere working electrode, R , is largest close to the electrode surface and proportional to ρ/r , where ρ is the specific resistivity. Thus, τ_{cell} is directly proportional to r and it is therefore smaller for ultramicroelectrodes than for microelectrodes. In LSV and CV, this means that larger sweep rates, typically up to 1 MV s^{-1} can be employed (see Eq. 84), and in CA and DPSC, the use of smaller step times becomes possible as i_c fades away much faster (see Eq. 82). For the CV technique, these properties are illustrated in Figure 12, where cyclic voltammograms for a reversible redox couple were simulated for different sweep rates at a 10- μm hemi-spherical electrode. Note also that the ohmic drop presents a smaller problem for ultra-microelectrodes, since iR is proportional to r as long as the current is due to planar diffusion. When spherical diffusion takes over on a longer timescale, that is, when smaller sweep rates are employed in CV, i is directly proportional to r and iR becomes independent of r .

In summary, the applications of UMEs can be divided into four main groups: 1) Fast-transient techniques, 2) Conditions where the iR drop would prevent the use of normal microelectrodes, 3) Detectors for monitoring bulk concentrations, and 4) Sensors, where the small dimension of the electrode is crucial.

2.4.1 Fast-Transient Techniques

The introduction of UME to the electroanalytical field has extended the applicability of techniques such as LSV, CV, CA, and DPSC. Because the cell time constant τ_{cell} as well as the iR loss are smaller for UMEs than for the normal-sized electrodes, it

becomes possible to employ larger sweep rates in LSV and CV up to 1 MV s^{-1} and smaller step times ($>1 \text{ }\mu\text{s}$) in CA and DPSC. For fast-transients experiments the diffusion mode is predominantly planar and the voltammograms recorded at a UME therefore have the same characteristics they would have had if a normal micro-electrode had been used. While the CA and DPSC techniques both enjoy the full advantage of the low τ_{cell} value offered at an UME, the LSV and CV techniques still have a problem concerning the nontransient component of i_c , that is, the constant contribution νC_{dl} (see Eqs. 82 and 83). Unfortunately, the faradaic current i_f increases only as a function of $\sqrt{\nu}$, meaning that the ratio i_f/i_c decreases with $\sqrt{\nu}$ as illustrated in Figure 12. In most situations it is possible to extract i_f from the total current, $i_{\text{total}} = i_f + i_c$. One procedure consists of subtracting the voltammogram recorded of the solution without any substrate being present ($i_{\text{total}} = i_c$) from the voltammogram obtained in the presence of the substrate. Alternatively, the contribution from i_c can be estimated from the baseline of the cyclic voltammogram recorded for the substrate, followed by a simple mathematical subtraction.

The early applications of fast CV mainly focused on the measurement of the peak-potential separation, ΔE_p , for the reduction or oxidation process of aromatic compounds, to obtain the pertinent standard heterogeneous rate constant k° from the relationship given in Table 2 [22]. The largest k° values of about 4 cm s^{-1} were found for the reduction of aromatic hydrocarbons such as anthracene at a gold electrode in acetonitrile. The peak-potential separation increased from the 58 mV expected for a reversible process at low ν to about 100 mV on going to ν values of 10 kV s^{-1} . This also shows that there is no real need for employing extremely large sweep rates in the determination of k° for the majority of compounds. Rather, it is important to ensure that the measurements at the lower sweep rates are not hampered by the contribution from spherical diffusion if a too small UME is used.

The above analysis also shows that for almost all applications of fast CV employing $\nu > 1 \text{ kV s}^{-1}$, the quasi-reversible or irreversible nature of heterogeneous electron transfer reactions must be considered. In particular, this becomes important when fast CV is used in a kinetic analysis of fast homogeneous follow-up reactions. The extraction of the relevant rate constants is complicated by the mixed kinetic control of the electrode process and the chemical reaction. As a result, the number of parameters involved in the fitting procedures is increased considerably and with it the possibility of introducing errors.

Savéant *et al.* have studied the reduction of aryl halides and 4-nitrobenzyl chloride by fast CV, and found that the mechanism follows an E_qC_i pathway, where the chemical step consists of a cleavage reaction of the radical anion generated in the first heterogeneous step [23]. To obtain the cleavage rate constant, k_c , the experimentally obtained voltammograms were compared with simulated voltammograms, which involved the adjustment of a number of parameters at the same time; E° , α , k° , k_c , and C_{dl} . The only way to lower the uncertainty on the determination of so many parameters is to carry out the procedure for a series of voltammograms recorded at different sweep rates, even though this work may be tedious and rather time-consuming.

The development of UMEs has considerably improved the possibility of detecting short-lived intermediates, no matter if they disappear in first-order or second-order

processes. In normal CV, where a sweep rate of at most 1000 V s^{-1} can be applied, electrogenerated intermediates with lifetimes larger than 1 ms can be detected directly. This corresponds to first-order rate constants smaller than 10^3 s^{-1} or second-order rate constants smaller than $10^6 \text{ M}^{-1} \text{ s}^{-1}$ on the assumption that the concentration of the substrate is in the millimolar range. In fast CV employing UME, sweep rates as high as 10^6 V s^{-1} can be applied, this lowers the detectable lifetime of intermediates to 1 μs . When converted to first- and second-order rate constants, this corresponds to values of 10^6 s^{-1} and $10^9 \text{ M}^{-1} \text{ s}^{-1}$, respectively. Should a first-order reaction proceed by a rate constant that is larger than 10^6 s^{-1} , there would be no access to its determination by fast CV. One then has to resort to an indirect method such as redox catalysis (see Section 2.7). For electrogenerated intermediates undergoing a second-order reaction, the situation is simpler, as the upper limit on the rate constant is set by the diffusion together of two species. The maximum rate constant is simply equal to the diffusion-controlled limit, k_d , given in Eq. 85, where N_A is Avogadro's number, D is the sum of the diffusion coefficients of the two reactants, and δ is the distance between the reactants at the closest approach. For many solvents, including *N,N*-dimethylformamide and acetonitrile, k_d is about $10^{10} \text{ M}^{-1} \text{ s}^{-1}$. The upper limit is thus almost within reach of the CV method when UMEs are used.

$$k_d = 4\pi N_A D \delta \quad (85)$$

Dimerization reactions are among the simplest second-order processes. In electrochemistry they are commonly observed when cationic substrates are reduced or anionic substrates are oxidized to neutral short-lived radical intermediates that are prone to fast dimerization. To determine the relevant second-order rate constant, the mechanism should be assessed first. As discussed in Section 2.3, a convenient approach consists of measuring the diagnostic criteria, $dE_p/d \log \nu$ and $dE_p/d \log C_O^*$, at an ordinary microelectrode. This often allows the various possible mechanisms to be distinguished, that is, in this case, the dimerization processes DIM1, DIM2, and DIM3. Afterwards, two different strategies based on UMEs can be adopted for evaluation of the rate constant for the dimerization process. In the first approach, the sweep rate is increased until the reaction mechanism is shifted from the KP to the KI zone where partial reversibility is observed. The rate constant can then be obtained from a comparison with simulated voltammograms. The second approach is to increase the sweep rate further until full reversibility is achieved in the DP zone. The standard potential E_O° is measured as the midpoint between $E_{p,a}$ and $E_{p,c}$. Then, from the potential displacement of E_p relative to E_O° observed at lower sweep rates, it is possible to calculate the rate constant with the appropriate equation. For instance, for a DIM1 mechanism, Eq. 69 applies. The latter method is rather uncertain, even though E_p is measured at microelectrodes at low sweep rate with a high accuracy. This is due to the appreciable uncertainty associated with the determination of E_O° ; even a small deviation in the measured potential displacement ($E_p - E_O^\circ$) such as 5 mV will result in an error of 80 % on the rate constant determined.

In the DPSC technique, the advantage of employing UMEs is that the cell time

constant $\tau_{\text{cell}} = RC_{\text{dl}}$ is diminished. For DPSC this offers a real advantage compared to the potential sweep experiments, since the capacitive current contribution is purely transient in its nature. This means that i_c is appreciable just after the potential steps, but then drops to zero as an exponential function of τ_{cell} (see Eq. 82). To ensure that the current measured is purely faradaic, the step times used should always be at least 10 times larger than τ_{cell} . As discussed for ordinary microelectrodes, it is also advantageous to adjust the potentials in DPSC so the heterogeneous electrode processes occur diffusion-controlled regardless of the value of k° and α . This reduces the number of variables and simplifies the simulation procedure considerably. While $10\tau_{\text{cell}}$ sets the lower limit of the time window, the upper limit is often set by the time at which the spherical diffusion process starts to prevail. Strictly speaking, this is so only from the point of view of convenience, since the spherical diffusion could be accounted for. On the assumption that the spherical diffusion should contribute less than 5 % to the total current, the step time should never exceed $\frac{(0.05r)^2}{\pi D_O}$. The two limits together define, for a given electrode size, the time window in which Cottrell behavior can be expected and the contribution from the capacitive and the spherical current is negligible (Eq. 86).

$$10\tau_{\text{cell}} < \tau < \frac{(0.05r)^2}{\pi D_O} \quad (86)$$

As discussed previously for the DPSC technique, a variation in τ of at least a factor of 130 is required for a complete transition from the KP to the DP zone through the KI zone. In practice, this is accomplished only if at least two different-sized UMEs are used.

The DPSC technique with UME has been employed by Savéant *et al.* [24] and Forster [25] in the study of the reduction process of various pyridinium cations. The rate constant k_{dim} for the dimerization of the radicals formed upon reduction was found by fitting to a working curve for a DIM1 mechanism as illustrated in Figure 13 for 1-methyl-4-*tert*-butylpyridinium. For this particular case, $k_{\text{dim}} = 6.4 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$. Two UME's with diameters of 5 and 17 μm were used to cover the range of step times from 3 μs to 3 ms. Note that the contribution to the flux from spherical diffusion at 3 ms for the 17- μm diameter UME becomes somewhat higher than 5 %.

Although the DPSC technique with UME has some advantages over fast CV with respect to cell time constant, ohmic drop, and slow heterogeneous kinetics, the technique has rarely been used. The main reason for this is that DPSC is a "blind" technique, where it is difficult to distinguish between a variation in the real response and experimental artefacts such as adsorption or changes in C_{dl} .

2.4.2 Applications of UME in Resistive Media and under Industrial Conditions

The ohmic drop presents a severe problem in electrochemistry, in particular when large electrodes are used. In the worst case, all the power of the potentiostat is lost

Figure 13. Double potential step chronoamperometry of 1-methyl-4-*tert*-butylpyridinium at a 5- μm (\square, \triangle) and a 17- μm ($\blacksquare, \blacktriangle$) diameter gold disk electrode. Variation of the normalized current ratio $R(=P')$ with step time $\theta(=\tau)$. From C. P. Andrieux, P. Hapiot, and J.-M. Savéant, *J. Phys. Chem.* 92:5992 (1988) [24].

in heating of the cell solution in a resistive manner. From the very early days of organic electrochemistry, this problem forced electrochemists to work in dipolar solvents. In particular, solvents like *N,N*-dimethylformamide, acetonitrile and dimethyl sulfoxide were and still are used extensively, because their aprotic nature allows the electrogeneration of relatively stable basic intermediates or products. Supporting electrolytes such as large tetraalkylammonium ions are added in high concentrations of 0.1 M, to raise the conductivity to an acceptable level for the electrochemical measurements. Still, in CV the voltage drop between the working electrode and the reference electrode becomes a severe problem at high sweep rates since the current, i , increases as a function of sweep rate. The cyclic voltammograms recorded at ordinary microelectrodes are distorted significantly when ν is larger than 1 V s^{-1} , and although different compensation procedures can be employed, the problem is never completely solved. The problem is diminished considerably if UMEs rather than microelectrodes are employed, because the iR voltage drop is proportional to r . In general, for sweep rates below 1000 V s^{-1} , no compensation is necessary when UMEs are used. However, for higher sweep rates, this is not the case, and some kind of electronic or mathematical correction of the electrode potential is needed. Moreover, a new problem arises, because the usual way of carrying out the on-line iR compensation by means of a positive feedback circuit may not function at the largest sweep rates applied in fast CV, because of band-pass limitations of the potentiostat.

Although the iR problem is therefore not completely eliminated for UMEs, there are still so many benefits from the reduced ohmic drop, that new interesting areas of applications within the electrochemical field have emerged. One such area pertains to the study of electrochemical processes in nonpolar solvents. For a long period, the use of dipolar organic solvents containing large amounts of supporting electrolytes has tended to separate organic electrochemistry from the field of classical organic chemistry where nonpolar solvents like ethers and hydrocarbons are frequently used. Also, from a mechanistic point of view, a wider selection of solvents would be desirable, so that solvent effects could be used for distinguishing between polar and nonpolar mechanisms. Finally, it would allow mechanistic investigations of ion-pairing phenomena in nonpolar solvents to be carried out.

The resistivity of a medium is related to 1) the solvent polarity, 2) the concentration of the supporting electrolyte, and 3) the solvent viscosity. One of the first breakthroughs was made by Parker as early as 1977, who employed a small micro-electrode (not yet an UME) for recording cyclic voltammograms of the reduction of perylene in benzene containing 0.1 M tetrabutylammonium perchlorate [26]. This new electrochemical development was not appreciated until later in the 1980s, when the development of UMEs made detailed electroanalytical studies in nonpolar solvents such as toluene [27, 28], hexane [27], and mineral oil [29] possible. The studies were extended to glasses, gels, and other highly viscous media, with the interesting feature that the cyclic voltammograms remained transient and peak-shaped, even if small sweep rates were applied. This is explained by the very small diffusion coefficients of molecules in a highly viscous medium being inversely proportional to the solvent viscosity. As a result, the growth of the diffusion layer is slow, and the onset of spherical diffusion occurs later. The presence of supporting electrolytes in concentrations of 0.001–0.7 M was still necessary for carrying out the measurements in nonpolar solvents, and it also required the tailoring of new types of supporting electrolytes such as dinonylnaphthalenesulfonic acid/trioctylphosphine oxide and tetrahexylammonium perchlorate that could be solvated and sufficiently dissociated in these solvents [27, 30].

The diminished need for high concentrations of supporting electrolyte in electrochemical measurements with UMEs has an interesting implication on the mode of mass transfer. Normally, mass transport of the electroactive redox pair, O/R, to the electrode, is governed by diffusion, while the migrational flux is precluded by the use of a large excess of the supporting electrolyte. The current going through the cell in the bulk solution is completely based on the migration of the ions from the supporting electrolyte. If no or only little supporting electrolyte is present, ions other than the electrolyte have to take over the current transport. Suppose that O is a positively charged species, then the migration of O will increase the total mass transport of O to the electrode surface and enhance the overall reduction rate to afford the neutral R. During this reduction process, the number of ions in the diffusion layer will change significantly and further increase the migrational flux of O. In other words, there is an intimate coupling of the diffusion and migration processes for the redox pair O/R, because either O or R will be charged.

A third effect to consider is the liquid junction potential that arises between the solution and the reference electrode because of the different concentrations of elec-

trolyte at the two places. This effect, as well as the ohmic loss and the intimate coupling of migrational and diffusional fluxes may substantially distort the recorded voltammograms. In steady-state measurements of limiting currents, the problem is somewhat simplified, because the exact electrode potential is not important and only the effect of the coupled diffusional and migrational fluxes need to be solved [31–33]. In all other cases where an exact knowledge of potentials is required, all three effects should be considered [34].

The fact that the iR drop is a smaller problem for UMEs compared to microelectrodes has another straightforward advantage, the substrate concentration can be increased substantially; this makes the performance of electroanalytical studies under conditions similar to industrial conditions possible. For instance, the industrially important hydrodimerization of acrylonitrile to adiponitrile takes place at high concentrations in aqueous medium in the presence of tetraalkylammonium salts that form an aprotic medium in the vicinity of the electrode surface. The mechanism consists of a dimerization reaction of the radical anions of acrylonitrile formed upon reduction of acrylonitrile in the aprotic tetraalkylammonium layer, followed by protonation of the dimer in the aqueous phase (Eq. 87). However, at low to moderate concentrations of acrylonitrile, a change in mechanism occurs in favor of a two-electron reduction of acrylonitrile to propionitrile (Eq. 88).

Unfortunately, the industrial process depicted in Eq. 87 could not be studied by classical electroanalytical techniques due to the high concentrations of acrylonitrile employed. Rather, one had to resort to the use of other olefins as model compounds that could form relatively stable radical anions in an aprotic medium where the protonation reaction was suppressed. However, it would be reasonable to question the industrial relevance of such studies, since the olefins selected are different from acrylonitrile. Montenegro and Pletcher therefore chose another approach using a hemispherical UME as the electroanalytical tool [35]. In this manner, the substrate concentration could be raised to a level compatible with the industrial process. In Figure 14 the steady-state voltammogram of a 1.5 M aqueous solution of acrylonitrile (+ tetraalkylammonium salt) is shown; although the shape of the wave is somewhat distorted because of the presence of the nearby discharge of the medium, the plateau current, I_L could be extracted. These values of I_L were normalized by division with the different concentrations C used in the experiments according to the theoretical expression given in Eq. 89 for a hemi-spherical UME.

$$I_L = 2\pi r n F D C \quad (89)$$

From these data, a plot of I_L/C versus C could be constructed as shown in Figure 15. As seen, a gradual shift from $n = 2$ at $C < 0.5$ M to $n = 1$ at $C > 1.2$ M occurs,

Figure 14. Plot of i - E curve recorded at a Hg ultramicroelectrode with area $8 \times 10^{-7} \text{ cm}^2$ for acrylonitrile (1.5 mol dm^{-3}) in an aqueous solution of Na_2HPO_4 (15 %)/ Bu_4NHSO_4 (0.4 %), pH 7, sweep rate 50 mV s^{-1} . From M. I. Montenegro and D. Pletcher, *J. Electroanal. Chem.* 248:229 (1988) [35].

that is the reaction shown in Eq. 88 is dominant when a low concentration of acrylonitrile is used, whereas the target reaction (Eq. 87) prevails at high concentrations. Interestingly, in the absence of the tetraalkylammonium salt, n is always two, regardless of the concentration. This shows that the formation of a hydrophobic layer by the tetraalkylammonium cations at the electrode surface is essential for creating the optimum non-acidic conditions for the production of adiponitrile in the dimerization reaction of two radical anions of acrylonitrile. The investigation confirms in a beautiful way the conclusions known already from process optimization in industry, and illustrates the prospects of using such a methodology in the investigation of other industrial processes prior to scale-up.

2.4.3 Steady-State Measurements at UMEs for Monitoring Slow Homogeneous Reactions

UV spectroscopy is often the technique of choice when relatively slow homogeneous reactions should be monitored, but sometimes the use of alternative and different approaches would be desirable. For instance, this situation arises if the species studied are without characteristic UV absorption bands or if the relevant bands are overlapped by the spectrum of other reactants, intermediates and products. In that case, electrochemical monitoring might provide an attractive alternative because of its ease and selectivity.

Figure 15. The normalized plateau current, I_L/C , (proportional to n) versus the concentration (C) for acrylonitrile in aqueous Na_2HPO_4 (15 %) / Bu_4NHSO_4 (0.4 %), pH 7. From M. I. Montenegro and D. Pletcher, *J. Electroanal. Chem.* 248:229 (1988) [35].

The steady-state current measured at a UME for a given electroactive species is given by Eqs. 48 and 89 for a disk and a hemi-spherical UME, respectively, that is, the plateau current is proportional to the bulk concentration. This is also true if other steady-state techniques like the rotating disk electrode (RDE) technique or polarography are employed. The monitoring of steady-state plateau currents should therefore provide the same kind of kinetic information that would have been obtained had the UV absorption of the species been monitored. While the steady-state behavior at an RDE arises because of convection due to stirring, it is attained at an UME because of spherical diffusion. The UMEs have the advantage that measurements also can be carried out in nonpolar solvents such as tetrahydrofuran or toluene. For an RDE, the larger electrode area combined with the enhanced mass transport due to convection results in larger plateau currents that are incompatible with the high resistance of nonpolar solvents.

Two strategies have been adopted for kinetic measurements. Either the electrode potential can be adjusted so that only the steady-state current is measured as a function of time, or the potential might be scanned continuously with the recording of steady-state voltammograms at certain time intervals. The first strategy outlined

has been used by the present authors to monitor the electron-transfer reaction between aromatic radical anions $A^{\bullet-}$ and alkyl halides RX [36]. The relevant reactions are depicted in Eqs. 90–92 with the rate law for the consumption of $A^{\bullet-}$ given in Eq. 93. Since the reactions shown in Eqs. 91 and 92 are always much faster than the reaction given by Eq. 90, the steady-state approximation can be applied to R^{\bullet} , to lead to the simplified differential expression shown in Eq. 94.

$$\frac{dC_{A^{\bullet-}}}{dt} = -k_{ET}C_{A^{\bullet-}}C_{RX} - (k_{91} + k_{92})C_{A^{\bullet-}}C_{R^{\bullet}} \quad (93)$$

$$\frac{dC_{A^{\bullet-}}}{dt} = -2k_{ET}C_{A^{\bullet-}}C_{RX} \quad (94)$$

$$C_{A^{\bullet-}} = C_{A^{\bullet-}}(0) \exp(-2k_{ET}C_{RX}t) \quad (95)$$

$$i = i_0 \exp(-2k_{ET}C_{RX}t) \quad (96)$$

On the assumption that $C_{A^{\bullet-}} = C_{A^{\bullet-}}(0)$ at $t = 0$ and $C_{RX} \gg C_{A^{\bullet-}}(0)$, Eq. 94 may be integrated to give Eq. 95. Substituting the concentration with the plateau current in Eq. 95 leads to the simple relationship (Eq. 96) between the observable parameter, i , and the rate constant k_{ET} . The parameter i_0 is the current measured at $t = 0$.

The first step in the experimental procedure consists of preparative electrolysis of the aromatic compound A to $A^{\bullet-}$. The preparative potentiostat is then disconnected and a UME is inserted into the cathodic compartment. The steady-state oxidation current of $A^{\bullet-}$ is recorded as a function of time for a certain time period to ascertain that the stability of $A^{\bullet-}$ is high. If this is indeed the case, the alkyl halide RX is added to the solution while it is stirred for a few seconds to assure that homogeneous conditions apply for the reaction of Eq. 90. The recorded current is observed to decay exponentially towards zero. A plot of $\ln i$ versus t is shown in Figure 16 for four different combinations of aromatic compounds and sterically hindered alkyl halides. From the slopes of the straight lines, $-2k_{ET}C_{RX}$, k_{ET} values can readily be obtained. The method is useful for the study of relatively slow reactions with $k_{ET} < 10 \text{ M}^{-1} \text{ s}^{-1}$.

The second strategy adopted for kinetic measurements involves the recording of complete voltammetric waves at certain time intervals rather than continuous measurement of the plateau current. This leads to a poorer time resolution but the advantage is that less charge is passed through the UME, and therefore the problems associated with fouling of the electrode surface should be smaller. The approach also opens the possibility of regenerating the electrode surface electrochemically by polarization of the electrode potential. This method has been used by Amatore and Pflüger in an investigation of the oxidative addition of substituted iodobenzenes (ArI) to tetrakis(triphenylphosphine)palladium(0) in toluene + 0.06 M tetrahexylammonium tetrafluoroborate [28]. In Figure 17, the i versus t curve is shown,

Figure 16. Current decay curves: the natural logarithm of the steady-state oxidation plateau current of radical anions (mediators) plotted against time (s) for the following four combinations of mediator/substrate: benzophenone/1-bromo-2,2-dimethylpropane (+); perylene/1-bromo-2,2-dimethylpropane (x); perylene/1-bromoadamantane (□) and quinoxaline/2-chloro-2-methylpropane (O). All measurements were obtained with a 10- μm platinum disk electrode in DMF/0.1 M Bu_4NBF_4 at 22°C. From S. U. Pedersen and K. Daasbjerg, *Acta Chem. Scand.* 43:301 (1989) [36].

where each “spike” corresponds to a potential scan at the gold disk UME in the range from -2.7 to $+0.2$ V vs Ag/Ag^+ . The plateau current is recorded at the upper potential limit. The decay of i corresponds to an overall second-order process, first order in both $\text{Pd}(0)$ and ArI .

2.4.4 Sensors

In biology and medicine, UMEs were employed at an early point, although the special features of small-sized electrodes were not recognized until later. The main motivation for using UME was the possibility of placing an electrode in biological tissue to monitor the concentrations of electroactive signal substances present in such environments. The UMEs that are used for *in vivo* studies are usually made of carbon fibers, because this electrode material is less likely to be blocked by adsorption of proteins. The carbon fiber with typical diameter of 10 μm is melted into soft glass, where the end is cut and polished. The size of the overall arrangement may amount to

Figure 17. Variation of the concentration of $\text{Pd}^\circ(\text{PPh}_3)_4$ as a function of time during its reaction with *p*-iodotoluene in toluene/0.06 M Hex_4NBF_4 at 25°C , monitored electrochemically at a $5\text{-}\mu\text{m}$ -radius gold-disk UME: a) Display of the voltammograms recorded from -2.7 to $+0.2$ V vs Ag/Ag^+ with a sweep rate of 50 mV s^{-1} as a function of time. In the inset, two successive voltammograms are shown (the cathodic current portion is deleted for simplification) together with the picture of the potential/time scan. b) The resulting variation of the $\text{Pd}^\circ(\text{PPh}_3)_4$ concentration is depicted as a function of time, where the solid line corresponds to the calculated response. From C. Amatore and F. Pflüger, *Organometallics* 9:2276 (1990) [139].

ca. $70\text{ }\mu\text{m}$ in diameter, sufficiently small for its implantation in tissue without causing severe damage and at the same time sufficiently large to ensure that only extracellular processes are monitored. Among the substances studied in this manner are the catecholamines (dopamine, norepinephrine, and epinephrine) and their acid and alcohol metabolites, ascorbic acid, uric acid, and 5-hydroxytryptamine. As ongoing work of the Wightman group, the secretion of 5-hydroxytryptamine by neurotransmitters has been investigated, in which the timing and quantity of neurotransmitter bursts could be characterized [37].

The scanning electrochemical microscopy (SECM) technique introduced in recent years by Allen Bard is another area where the smallness of the electrode is essential [38]. The principle in SECM is a mobile UME inserted in an electrolyte solution. The UME is normally operated in a potentiostatic manner in an unstirred solution so that the current recorded is controlled solely by the spherical diffusion of the probed substance to the UME. The current can be quantified from Eqs. 48, 49, or 89 as long as the electrode is positioned far from other interfaces. However, if a solid body is present in the electrolyte solution, the diffusion of the substance to the UME is altered. For instance, when the position of the UME is lowered in the z direction, that is, towards the surface of the object, the diffusion will be partially blocked and the current decreases. By monitoring of the current while the electrode is moved in the x - y plane, the topology of the object can be graphed. The spatial resolution is about $0.25\text{ }\mu\text{m}$. In one investigation carried out by Bard *et al.*, the

typography of stomata on the surface of grass and leaves was studied. Upon stimulation of the stomatal guard cells by light radiation they were able to detect the evolution of oxygen from the individual cells from its reduction at the UME [39].

The SECM technique has also found many other applications [40]. It has been used to modify the surface of objects and in the investigation of electrode processes taking place at other electrode surfaces. In the latter case, this has made a detailed mapping of concentration profiles possible. Recent developments by Unwin *et al.* have also shown that SECM, when operated as in a DPSC experiment, can be used in the study of reactions occurring at liquid/liquid and liquid/gas interfaces [41]. During the first potential step, the substance O is reduced (or possibly oxidized), under diffusion control, to R at the UME that is placed near the interface. The R formed in this way may then interact with the interface by adsorption or a chemical reaction; the progress of these processes can be evaluated by monitoring of the current pertaining to the reoxidation of R to O during the second potential step. In this manner, the SECM-DPSC technique has been used to study the charge-transfer kinetics occurring between two immiscible electrolyte solutions. The driving force for these processes is provided by the potential difference between the two phases, and it can be adjusted by a change of the galvanic potential of the liquid junction. Rusling *et al.* have carried out extensive studies on the possibility of performing catalytic electrochemical reactions in aqueous micro-emulsions when the microphases are separated by a surfactant [42]. However, quantification is difficult because of the uncertainties associated with the characterization of the interface, unless one turns to the SECM-DPSC method. Bard *et al.* have performed similar studies on long-range electron transfer through phospholipid monolayers at the interface between two immiscible electrolyte solutions [43].

Perhaps the most astonishing achievements within the field of small electrodes are the electrochemical detection of single molecules [44], single reactions [45] or single-electron-transfer events [46] with the use of so-called nanodes with radii in the order of a few nanometers. The nanode employed in the electrochemical detection of single molecules was prepared by electrochemical sharpening of an 125 μm Pt-Ir wire. The wire was completely coated with wax or polyethylene before the electrode surface was exposed electrochemically in an STM procedure. The electrode surface of the nanodes was slightly recessed (10 nm) relative to the insulating coating, as depicted in Figure 18. It was therefore possible to trap one or two electroactive molecules such as of (trimethylammonio)methyl ferrocene, Cp_2FeTMA in the small enclosed volume (ca. 10^{-18} cm^3) formed when the nanode surface was moved close (within 10 nm) to a conductive substrate. The electroactive molecules were then able to transport electrons between the nanode and the substrate, about 10^7 times/s, resulting in a total current in the order of 1 pA.

The same authors have recently studied the effect of placing two nanodes in series in an electrolyte solution containing micromolar concentrations of an electroactive reagent such as $\text{Cp}_2\text{FeTMA}^+$. Then the *i-E* characteristics for small potential differences have a staircase shape, where the height corresponds to the transfer of one electron.

Wightman *et al.* [45] observed a single chemical reaction between two molecules. The reaction was the electron transfer between an electrogenerated aromatic radical

Figure 18. Idealized schematic illustration of the tip geometry and the tip-substrate configuration used. From F. F. Fan and A. J. Bard, *Science* 267:871 (1995) [44].

anion, A_1^- and an aromatic radical cation, A_2^+ , where A_1 may be the same compound as A_2 or different. When the two radical ions collide, electron transfer takes place immediately and either the non-emitting triplet state of the parent compounds or the corresponding excited singlet state that relaxes to the ground state by photo emission are formed. The substrate selected in this particular study was 9,10-diphenylanthracene (DPA), which was first oxidized to DPA^+ over 500 μ s, followed by reduction to DPA^- over the next 50 μ s. The thickness of the diffusion layer pertaining to DPA^+ , δ_{DPA^+} , is approximately 1 μ m, as calculated from Eq. 23. Since the subsequent reductive pulse is somewhat shorter, the diffusion layer of DPA^- will grow out into the diffusion layer of DPA^+ , as depicted in Figure 19, until $\delta_{DPA^-} \approx 300$ nm. This corresponds to a volume of the DPA^- diffusion layer of approximately 2×10^{-14} dm^3 , as the radius of the disk electrode is 5 μ m. The photons emitted during the 50- μ s reductive pulse were recorded with high temporal resolution and the events were shown to be stochastic. A Poisson distribution was observed, which is characteristic of discrete, random, and independent events. Recently, chemiluminiscence has also been used to monitor the shapes of small electrodes [47, 48].

2.5 Hydrodynamic Electrochemical Techniques

So far the electrochemical techniques described have been based on diffusion as the mode of mass transfer of the electroactive reactants, that is, the concentration profiles develop according to Fick's second law (Eq. 22). The thickness of the diffusion

Figure 19. A radical anion of 9,10-diphenylanthracene ($R^{\bullet-} = DPA^{\bullet-}$) is electrogenerated during the cathodic potential pulse and diffuses into the layer of the radical cation of 9,10-diphenylanthracene ($R^{\bullet+} = DPA^{\bullet+}$) electrogenerated during the anodic potential pulse. From M. M. Collinson and R. M. Wighman, *Science* 268:1883 (1995) [45].

layer grows as $\sqrt{2D_0t}$ (Eq. 23) and, thus, the maximum flux of the reactant decreases as $t^{-1/2}$ (Eq. 39). The migration is eliminated by addition of an inert electrolyte to the solution and the contribution from convection can largely be neglected if the solution is not stirred. Natural convection always takes place to some extent because of vibrations and the presence of density gradients and temperature fluctuations in the solution, but these contributions to the flux are of no importance until the diffusional flux has diminished to a low level. In chronoamperometry, this happens at microelectrodes when the step time is larger than 5 s and the flux of the electroactive reactant is decreased by more than two orders of magnitude compared to the flux after 1 ms. At this point, the measured current will not be a function of $t^{-1/2}$ any longer as predicted by the Cottrell equation (Eq. 39), but rather attain a steady-state value. The contribution from spherical diffusion may help to attain this steady-state situation.

When forced convection is applied in the cell by means of, for instance, a magnetic stirrer, the flux due to convection increases and may become the dominant constituent of the total flux even after just a few ms. This results in a steady-state situation, where the diffusion layer stops growing. (If the convection is laminar, then the solution adjacent to the electrode surface will not move relative to the electrode, and diffusion becomes the only mode of mass transport in this thin layer.) Overall, the effect of convection is thus to shrink the thickness of the diffusion layer, resulting in larger concentration gradients in the diffusion layer with much more efficient mass transport of the electroactive species. In other words, the current densities that can be accomplished in stirred solutions are much higher than in unstirred.

Many modes of convection have been implemented in electrochemical cells in terms of stirring, rotation, vibration, and so forth. They may be divided into two main groups according to our ability to describe the mass transport mathematically. If a magnetic bar is used to stir the solutions as in preparative electrolysis (PE), the

mass-transport process is not well defined, owing to fluctuations. In this case, it is impossible to calculate the concentration profiles in the cell and the exact influence of the convection is unpredictable, although general and averaged effects might be discussed [49–55]. For some special convection modes, as observed for the rotating disc electrode (RDE), the development in the concentration profiles can be predicted precisely. Another example is the dropping mercury electrode used in classical polarography, where the effect of the convection (i.e., a growing drop) can also be described mathematically. In the following, PE and the RDE technique will be discussed in further details; readers interested in polarography are referred to Refs. [1, 56, 57, 58].

2.5.1 Preparative Electrolysis

Preparative electrolysis differs from electroanalytical techniques in that the aim is to electrolyze all the electroactive substance present in the solution rather than just the small fraction present in a thin diffusion layer adjacent to the electrode surface. To achieve bulk electrolysis, a large A/V (electrode area to cell volume) ratio is required in combination with enhanced mass transport; this is accomplished by the solution being stirred with a magnetic bar. Preferentially, exhaustive electrolysis on laboratory scale should provide the products in a yield that enables their identification and quantification by the common spectroscopic and chromatographic methods. Because of the continuous developments in the sensitivity of these methods, a few milligrams of the substance is often sufficient. The total charge, Q , used in exhaustive electrolysis is obtained by integration of the current with a coulometer. From Q , it is then possible to calculate the number of electrons, n , consumed by one substrate molecule in the electrogeneration of the product, on the basis of Eq. 97, where m is number of moles of the substrate in the cell.

$$n = \frac{Q}{F \cdot m} \quad (97)$$

Note that the calculated value of n might be a fraction if the current efficiency is less than 100 % or the mechanism followed is complex. Preparative electrolysis can be performed under potentiostatic or galvanostatic conditions. In the former case, the use of a potentiostat ensures that the potential of the working electrode relative to a reference electrode is held at a constant value during the whole electrolysis process independently of the current supplied. Preferentially, the potential should be selected so that the substrate can be electrolyzed without the products or the medium being reduced or oxidized at the same time. It is possible by proper potential adjustment to control the fraction of electrolysis X which is defined according to Eq. 98 as the fraction of the substrate transformed during electrolysis.

$$X = \frac{C_O^*(\text{initial}) - C_O^*(\text{end})}{C_O^*(\text{initial})} = \{1 + 10^{(E - E_O^\circ)n/59.2}\}^{-1} \quad (98)$$

If the electrode potential, E , is 118 mV smaller than E_O° for the preparative reduction of O, then X is 99 % or, expressed differently, only 1 % of O has not been transformed at the end of the electrolysis. Equation 98 is valid not only for fast (nernstian) but also for slow heterogeneous electrode reactions, since an equilibrium situation is always attained at the end of the electrolysis where the current is essentially zero. For an irreversible electrode reduction, the rate of electrolysis as expressed by the electrolysis current is, however, very low if $E - E_O^\circ$ is -118 mV. The employment of much higher overpotentials or mediated electrolysis (see Section 2.7) may then be required for achieving a reasonable rate of transformation.

The rate of transformation of O, $-\frac{\partial C_O}{\partial t}$, is proportional to $C_O(t)$. Consequently, $C_O(t)$ decreases exponentially with time during electrolysis, and the same is true for the potentiostatic electrolysis current, $i(t)$. The expression for $i(t)$ is shown in Eq. 99, where i_L is the limiting current at the start of the electrolysis ($t = 0$).

$$i(t) = i_L \exp\left(\frac{-Am_O t}{V}\right) \quad (99)$$

The time constant for the electrolysis depends on the A/V ratio and the phenomenological parameter, m_O , that describes the efficiency of the mass transport. While most small-scale electrolyses can easily be carried out under potentiostatic conditions, a galvanostatic approach is necessary for large-scale electrolysis, since it requires the use of higher current densities. Most potentiostats are not able to deliver currents higher than 2 A, but a galvanostat can be adjusted to sustain any value throughout the electrolysis. In the latter case, there is no need for the use of a reference electrode, as long as the current is used only for transforming substrate to product. The applied current, i_{ap} , should always be kept at or below the limiting current, i_L , for the substrate at any time during the electrolysis. The steady-state voltammogram of a typical galvanostatic electrolysis process is illustrated in Figure 20. The substrate O is reduced at -1.0 V to a product P which can be further reduced and, unfortunately, destroyed at -1.6 V. At -2.4 V, the medium (solvent and supporting electrolyte) discharge appears. During potentiostatic electrolysis, the potential is set to -1.2 V, which should ensure exhaustive electrolysis of O to P with an electrolysis fraction X larger than 99.9 %. If i_{ap} in the galvanostatic approach is adjusted to the limiting current of 100 mA, then soon after the onset of electrolysis, the effective potential will move from the initial -1.0 V to the second wave at -1.6 V and, as a result, some of the product P will be destroyed by the further reduction process. If i_{ap} is adjusted to 50 mA, the electrolysis takes longer, but the potential value will not move to the second wave until 50 % of O has been reduced. For $i_{ap} = 10$ mA, the selectivity is even higher, as 90 % of O can be reduced before the shift in the potential occurs; this is, however, at the cost of considerable extension of the electrolysis time. On industrial scale, where the use of galvanostatic electrolysis is obligatory, i_{ap} is normally adjusted during electrolysis according to in situ measurements of the concentration of O or some preprogrammed value. The optimal situation is attained when i_{ap} is always slightly lower than i_L . Another

Figure 20. Example of preparative electrolysis monitored by steady-state voltammetry. The curves shown are constructed but they could have been recorded with RDE, UME, or polarography for a substrate O that is reduced reversible at $E_O^\circ = -1.0$ V to a product that is reducible at -1.6 V. The medium is reduced at $E < -2.4$ V. The different curves correspond to a) Before the preparative electrolysis, b) after 50 % of O has been electrolyzed to product, and c) after exhaustive electrolysis of O to product.

approach consists of adding starting material to the electrochemical cell during the electrolysis so the same high value of i_{ap} can be sustained for a long period.

2.5.2 Rotating Disc Electrode

The essential components constituting the RDE system are a speed controller, a motor, and an electrode. The rotation speed (rounds per second, rps) of the motor is adjusted by means of the speed controller. The electrode which is shown in Figure 21 is a 3–5 mm diameter conducting disc imbedded in an insulating rod of teflon, plastic, or glass. The electrode rod is often mounted, so it is a direct extension of the motor axle, but a drive belt can also connect it. The electrical contact to the rotating working electrode is made with brushes of carbon-silver. The flow of the solution near the spinning electrode will be laminar if the Reynolds number, $R_e = r^2\omega/v_k$ is smaller than 200 000, where r is the radius of the disc electrode, ω is the angular rotation rate (rad s^{-1}), and v_k is the kinematic viscosity. For an aqueous solution at 20°C , v_k is equal to $0.01 \text{ cm}^2 \text{ s}^{-1}$ and, thus, the rotation rate ($2\pi\omega$) should be less than 300 000 rps to ensure laminar conditions. However, the practical limit is closer to 200 rps due to non-idealities imposed by the spinning rod.

When the electrode rod rotates, the solution close to the electrode surface is forced along with it, and because of the centrifugal force, it will be thrown outwards radially from the center of the electrode. From below, new solution is dragged to the electrode surface, as indicated by the arrows shown in Figure 21. Karman and

Figure 21. Schematic illustration of a rotating disc electrode (RDE). The stream arrows indicate the flow to the rotating disc.

Cochran mathematically described these movements of the solution in the cell under laminar conditions. The forced convection was included in the Nernst–Planck equation which allowed the calculation of the steady-state concentration profile depicted in Figure 22.

However, for most applications, the Nernst-approximated profile is used, in which the concentration is assumed to vary linearly in a diffusion layer with thickness, δ_{RDE} , given by Eq. 100.

$$\delta_{\text{RDE}} = 1.61 D_{\text{O}}^{1/3} \nu_k^{1/6} \omega^{-1/2} \quad (100)$$

The use of Fick's first law (Eq. 21) then provides the relation for the current i given in Eq. 101 where $C_{\text{O}}(0)$ is the concentration of O at the electrode surface.

$$i = n F A D_{\text{O}} \left(\frac{\partial C_{\text{O}}(x)}{\partial x} \right)_{x=0} = \frac{n F A D_{\text{O}} (C_{\text{O}}^* - C_{\text{O}}(0))}{\delta_{\text{RDE}}} \quad (101)$$

The plateau current, i_{pl} obtained when the polarization of the RDE is sufficient to

Figure 22. Concentration profile for O. The concentration of O is normalized with the bulk concentration and the distance to the electrode surface is normalized with the diffusion layer thickness $\delta_{\text{RDE}} = 1.61 D_{\text{O}}^{1/3} \nu_k^{1/6} \omega^{-1/2}$ (Eq. 100).

make $C_{\text{O}}(0) \approx 0$ can then be expressed as shown in Eq. 102 known as the Levich equation.

$$i_{\text{pl}} = \frac{0.602nFAD_{\text{O}}^{2/3}\omega^{1/2}C_{\text{O}}^*}{\nu_k^{1/6}} \quad (102)$$

Note that i_{pl} is proportional to C_{O}^* . If the electrode reaction of O is nernstian then Eq. 101 can be transformed into a relation between the applied potential, E , and i as shown in Eq. 103.

$$E = E_{\text{O}}^{\circ} + \frac{RT}{nF} \ln \frac{i_{\text{pl}} - i}{i} = E_{\text{O}}^{\circ} + \left(\frac{59.2}{n} \right) \log \frac{i_{\text{pl}} - i}{i} \text{ mV} \quad \text{at } T = 20^{\circ}\text{C} \quad (103)$$

The reversibility of a given system can be tested by plotting E against $\log \frac{i_{\text{pl}} - i}{i}$, where the slope ideally should be $59.2/n$ mV at 20°C . For quasi-reversible and irreversible electrode processes the slope will be substantially larger. A typical voltammogram for the reversible case is shown in Figure 23, where the standard potential is found at $i = i_{\text{pl}}/2$.

The RDE technique has found widespread use in analytical electrochemistry because of an excellent signal-to-noise ratio resulting from the enhanced mass transport. The RDE method has also been employed for monitoring concentrations in kinetic applications [59], as described for ultramicroelectrodes [60] and in the determination of the stoichiometry for electron-transfer reactions by means of redox titration [61]. The latter procedure will be described next.

Consider a reaction between an electrogenerated aromatic radical anion, $\text{A}^{\cdot-}$,

Figure 23. Typical RDE voltammogram (calculated) for the reversible reduction of O. The medium is reduced at $E < -2.3$ V. The standard potential E° for O can easily be measured at the point where the current, i is equal to half of the plateau current i_{pl} , as indicated by the dotted line. In this case $E^\circ = -1.0$ V.

and an alkyl halide, RX , where the parent aromatic compound A as well as other non-electroactive products are formed. The net reaction can be written as in Eq. 104, where the aim is to determine a , b , and c .

First, the aromatic compound A is added to an electrochemical cell equipped with an RDE. In Figure 24 the steady-state voltammogram recorded of a 50-mL solution containing $C_{\text{A},0} = 2$ mM is shown as the solid curve. The plateau current pertaining to A , $i_{\text{pl},\text{A},0}$, is -1 mA and the Levich equation, Eq. 102, can be used to relate $i_{\text{pl},\text{A},0}$ and $C_{\text{A},0}$, as shown in Eq. 105.

$$\frac{C_{\text{A},0}}{i_{\text{pl},\text{A},0}} = \frac{C_{\text{A}}}{i_{\text{pl},\text{A}}} = 2 \quad \left(\text{in } \frac{\text{M}}{\text{A}} \right) \quad (105)$$

Most of the A compound is then reduced preparatively in a one-electron process affording $\text{A}^{\bullet-}$. In Figure 24, the voltammogram recorded after passage of 9.5 C is shown as the dashed curve. To express $C_{\text{A}^{\bullet-},1}$ by the measurable $i_{\text{pl},\text{A}^{\bullet-},1}$ parameter, the ratio $D_{\text{A}}/D_{\text{A}^{\bullet-}}$ should be known. For most aromatic compounds it is close to one, and it is then possible to deduce the following relationship (Eq. 106) between the plateau currents and concentrations pertaining to both A and $\text{A}^{\bullet-}$.

$$C_{\text{A}^{\bullet-},1} = \frac{C_{\text{A},0}}{i_{\text{pl},\text{A},0}} \left(\frac{D_{\text{A}}}{D_{\text{A}^{\bullet-}}} \right)^{2/3} i_{\text{pl},\text{A}^{\bullet-},1} = 2 \left(\frac{D_{\text{A}}}{D_{\text{A}^{\bullet-}}} \right)^{2/3} i_{\text{pl},\text{A}^{\bullet-},1} \approx 2i_{\text{pl},\text{A}^{\bullet-},1} \quad \text{if } D_{\text{A}^{\bullet-}} \approx D_{\text{A}} \quad (106)$$

In this example, $i_{\text{pl},\text{A},1}$ is measured to be -0.1 mA, which means that 0.2 mM of A

Figure 24. Constructed example of a stoichiometric determination by means of the RDE technique. The solid curve illustrates the reversible reduction of A to $A^{\bullet-}$ taking place at $E^\circ = -1.0$ V. The plateau current $i_{pl,A,0}$ is proportional to $C_{A,0} = 2$ mM. The cell volume is 50 mL. The dashed curve is a RDE voltammogram recorded after preparative reduction of A to $A^{\bullet-}$, consuming 9.5 C. Finally, the dotted-line curve is a voltammogram recorded after 0.7 mM of the alkyl halide has been added and reacted with $A^{\bullet-}$.

is left unelectrolyzed in the cell, while the $i_{pl,A^{\bullet-},1}$ value of 0.8 mA corresponds to $C_{A^{\bullet-},1} = 1.6$ mM. Note that the apparent disappearance of 0.2 mM compound in the cell is due to the formation of nonelectroactive products during the electrolysis of A.

The substrate RX is now added in a concentration ($= 0.7$ mM) that ensures that some $A^{\bullet-}$ is left in the cell after completion of the reaction. That the latter condition is fulfilled can easily be seen from the third voltammogram recorded in Figure 24, where $i_{pl,A^{\bullet-},2} > 0$. It is found that $i_{pl,A,2} = -0.45$ mA and $i_{pl,A^{\bullet-},2} = 0.1$ mA, corresponding to $C_{A,2} = 0.9$ mM and $C_{A^{\bullet-},2} = 0.2$ mM, respectively. The stoichiometry for the reaction of Eq. 104 can now easily be extracted from Eq. 107, and the result is shown in Eq. 108 with $a = 2$, $b = 1$, and $c = 1$.

Half of the amount of $A^{\bullet-}$ must therefore be transformed into a non-electroactive product. Obviously, Eqs. 105 and 106 are valid only for this specific process, but similar relations can easily be found for other reactions. The RDE technique has found many other applications, for instance, ones concerning the transient signals obtained at short time intervals. The reader interested in such subjects as well as the ring-disc technique is referred to Refs. [1, 62].

2.6 Combination of Electrochemistry and Spectroscopy

The use of spectroscopic methods such as UV, IR, and EPR spectroscopy in combination with electrochemistry is a strong tool for the detection and characterization of intermediates and products. Even the electrode/electrolyte interface may be studied in this manner. The equipment can be classified into three types according to the exact setup of the two parts. The first type (Type 1), in which the electrogeneration is separated in time and place from the spectroscopic detection, can be employed in the study of products or longer-lived intermediates. In practice, the setup often consists of a flow cell connected to a cuvette by tubes. This approach requires the construction of the electrochemical flow cell while the spectroscopic cell and the spectrometer are commercially available. In the second type of equipment (Type 2), which is very useful in the study of short-lived intermediates, the spectroscopic detection occurs simultaneously with the electrogeneration within the diffusion layer of the electrode. This combination of methods is known as spectroelectrochemistry and it requires that the light from the spectrometer is able to penetrate the diffusion layer. Therefore, the electrode surface should either reflect the light or be optically transparent in terms of fine minigrids, lithographic–galvanic structures (LIGA) [63], or thin layers of metal films such as gold or oxides of tin. In the third type of equipment (Type 3), the electrogeneration and detection take place at the same time, but with the spectroscopic cell placed outside the diffusion layer of the electrode. Techniques such as pulse radiolysis, flash photolysis, modulated photolysis and photoelectron injection in combination with electrochemical detection modes have been described recently [64] and will not be covered herein.

2.6.1 Type 1

Electrochemical flow cells

One of the essential units in the Type 1 equipment is the flow cell that can be constructed in numerous ways depending on the specific requirements concerning flow rates, conversion efficiency, electrode material, and so forth. The present authors have used a flow cell where the housing was made of inert PCTE (Kel-F). Carbon fibers were used for the working electrode, and these were pressed tightly into a porous ceramic 50-mm tube with an inner bore of 5 mm and outer bore of 16 mm. The connection to the working electrode was made with a platinum wire. The counter electrode was a platinum net placed in a compartment outside the ceramic tube. A small reference electrode was placed downstream, so the flow cell could be operated both potentiostatically and galvanostatically. The electrolyte could be forced through the flow cell with syringes or by means of an HPLC pump [65].

Flow cell and EPR

The flow cell has been used in combination with EPR spectroscopy to study self-exchange electron-transfer reactions between aromatic radical anions in line-

Figure 25. Corrected EPR linewidth L_w vs the concentration of 2,5-di-*tert*-butyl-1,4-dimethoxybenzene $[A_i]$, measured for the self-exchange electron-transfer reaction between the substrate and its radical cation (A^+). The concentration of the latter was in all experiments equal to 0.05 mM in acetonitrile/0.1 M Bu_4NBF_4 . From the slope, k_{ET} is calculated to be $1.1 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$; this corresponds to a self-exchange reorganisation energy of $21.2 \text{ kcal mol}^{-1}$. From D. Jürgen, S. U. Pedersen, and H. Lund, *Acta Chem. Scand.* 51:767 (1997).

broadening experiments [66, 67] to obtain self-exchange reorganization energies. For this application it is very important that the concentration of the paramagnetic species is controllable and can be kept constant. One example is given in Figure 25, where the self-exchange reorganization energy was measured for 2,5-di-*tert*-butyl-1,4-dimethoxybenzene and the corresponding radical cation. Because of the separation of the electrochemical flow cell and the ESR cuvette, there is a finite transit time between the sites of generation and detection, which means that only radicals with a certain lifetime can be detected. The excellent sensitivity of the ESR apparatus allows the measurement of very low steady-state concentrations of the radical ions and the flow rate can be varied so that the kinetics of the decay reactions can be studied.

Flow cell and IR

The same electrochemical flow cell has also been used in combination with IR spectroscopy in a stopped-flow system [68, 69]. The purpose was to study the electrogeneration of the Collman reagent $Fe(CO)_4^{2-}$ obtained from the two-electron reduction of $Fe(CO)_5$. It was possible to monitor the consumption of $Fe(CO)_5$ and

Figure 26. Application of flow-cell and IR spectroscopy to study the reaction between the electro-generated Collman reagent, $\text{Fe}(\text{CO})_4$ ($\nu = 1741 \text{ cm}^{-1}$) and $\text{Fe}(\text{CO})_5$ ($\nu = 2018$ and 1993 cm^{-1}) to generate $\text{Fe}_2(\text{CO})_8^{2-}$ ($\nu = 1914$ and 1883 cm^{-1}). $\text{Fe}(\text{CO})_5$ (1 mM) is reduced in the flow cell to $1\text{mM } \text{Fe}(\text{CO})_4^{2-}$, which is mixed with 10 mM $\text{Fe}(\text{CO})_5$ in the IR cuvette. The medium was acetonitrile/0.1 M Bu_4NBF_4 . From C. Amatore, J. N. Verpeaux, and S. U. Pedersen, in *Novel Trends in Electroorganic Synthesis* (S. Torii, Ed.), Kodansha, Tokyo, 1995, p. 205.

generation of $\text{Fe}(\text{CO})_4^{2-}$. The reactions of $\text{Fe}(\text{CO})_4^{2-}$ with $\text{Fe}(\text{CO})_5$ were also monitored by IR spectroscopy and this is shown in Figure 26. The product was easily identified as $\text{Fe}_2(\text{CO})_8^{2-}$ and the rate constants for the reaction was then obtained under pseudo-first-order conditions to be $2.3 \text{ M}^{-1} \text{ s}^{-1}$. The reaction between $\text{Fe}(\text{CO})_4^{2-}$ and alkyl halides (RX) could likewise be studied and the products $\text{RFe}(\text{CO})_4$ and $\text{RCOFe}(\text{CO})_4$ could be identified, and rate constants could be measured [9, 68].

Flow cell and UV

The electrochemical flow cell has also been used in combination with a UV spectrophotometer to obtain accurate UV spectra for a considerable number of aromatic radical anions ($\text{A}^{\cdot-}$) in *N,N*-dimethylformamide [65]. A solution of 0.1 mM of the aromatic compound (A) was pumped with a constant flow rate through the electrochemical flow cell. The latter was operated galvanostatically so that the electrolysis current could be increased steadily until the absorbance of the reduced or oxidized species attained a maximum, as illustrated in Figure 27. The maximum corresponds to the situation where all A is reduced to $\text{A}^{\cdot-}$ (or to $\text{A}^{\cdot+}$ in the case of an oxidation). When the current is increased beyond the optimum value, a further reduction of $\text{A}^{\cdot-}$ to A^{2-} takes place, leading to the decrease observed in the absorbance of $\text{A}^{\cdot-}$. This may be accompanied by the appearance of the spectrum for A^{2-} , as in

Figure 27. Application of flow cell and UV spectroscopy to study the reduction of aromatic compounds in *N,N*-dimethylformamide/0.1 M Bu₄NBF₄: a) Plot of absorbance at $\lambda_{\text{max}} = 556$ nm and 732 nm, of the products obtained in the reduction of anthraquinone (▼) and anthracene (●), respectively, as the galvanostatic current to the flow cell is increased and a continuous flow of 5 mL min⁻¹ is maintained. The substrate concentrations are both 0.1 mM and the light path is 1 cm; b) and c) The absorption spectra of the product obtained from reduction of anthraquinone and anthracene, respectively, when the galvanostatic current is increased above the maximum required for generating the radical anion. The current is increased from 2.0 to 2.8 mA in steps of 0.2 mA and the development in the spectra is indicated with arrows. Isosbestic points are also indicated. For anthraquinone, the spectra of the radical anion and the dianion could be resolved whereas for anthracene the dianion is protonated and spectra of the radical anion and 9,10-dihydroanthracen-9-ide could be resolved [65].

the case of anthraquinone. Most other dianions, including 9,10-dihydroanthracen-9-ide, are protonated immediately to AH⁻, whose spectrum is then recorded. The results obtained are summarized in Table 4.

To summarize, the type 1 equipment, in which the spectroscopic detection is combined with an electrochemical flow cell, has the advantage that the experimental setup is relatively simple. The lower limit of the time window is ca. 5 s, with the major drawback that only relatively stable intermediates can be detected. On the other hand, this ensures that homogeneous conditions are always attained. If the lifetime of the intermediates is less than 1 s, they exist in a reaction layer within the diffusion

layer, and spectroscopic detection would require that the light passes through the diffusion layer. Then the method of choice would be spectroelectrochemistry.

2.6.2 Type 2

Spectroelectrochemistry

In spectroelectrochemistry, spectroscopic detection in the electrochemical cell occurs simultaneously with the electrochemical generation. Often the response is also monitored electrochemically, thus providing an even more detailed description of the intermediates produced. The spectroelectrochemistry technique has found widespread use; there are excellent reviews on the subject [70].

Spectroelectrochemistry can be accomplished in different ways. If the light is passed through an optically transparent electrode (OTE), as shown in Figure 28(A), the light will go through not only the diffusion layer containing the intermediate generated at the electrode, but also through the bulk solution where no intermediate is present. In this sense, the bulk solution presents nothing but a complicating factor, in particular if it is recalled that the thickness of the diffusion layer ($\delta < 0.1$ mm) is very small compared to the size of the bulk in normal cells. This has resulted in the design of special thin layer cells with such small physical dimensions, that the diffusion layer extends to the cell wall. The combination of an optically transparent electrode and a thin-layer cell is denoted an OTTLE (optically transparent thin-layer electrode) (see Figure 28(B)). The fact that the cell volume is very small compared to the electrode area has an interesting implication. Suppose a redox pair O/R is present in the cell, then changes in the electrode potential provide a facile way of controlling the concentration ratio of O and R at the electrode surface according to the Nernst equation. Because of the smallness of the cell and the restrictions imposed thereby on the diffusion layer, the concentrations of O and R everywhere in the cell will be the same as at the surface after a short while. In other words, the spectroscopic measurements pertain to equilibrium concentrations.

Figure 28. Configurations for spectroelectrochemistry. A) optically transparent electrode; B) optically transparent thin-layer electrode (OTTLE); C) Internal reflection spectroscopy, and D) specular reflectance spectroscopy.

Internal reflection spectroscopy

The principle underlying internal reflection spectroscopy is shown in Figure 28(C). The light beam is directed from the inside of an OTE at an angle greater than the critical angle, so that it is reflected at the electrode/electrolyte interface. The depth of the light into the solution is about $0.1\ \mu\text{m}$, which is much larger than the thickness of the double layer but smaller than the diffusion layer. For most applications such a path length is too short, and as a result, multiple reflections have to be used.

Specular reflectance spectroscopy

In specular reflectance spectroscopy, the intermediates are also monitored close to the electrode surface by spectroscopy, but here there is no need for an OTE, as ordinary well-polished disk electrodes will do the job. The light beam is directed towards the front of the electrode surface and is reflected as shown in Figure 28(D). The beam therefore transverses the diffusion layer twice, and the light path can be changed by variation of the angle of reflectance.

Diffusion-layer imaging

The diffusion-layer imaging technique which was developed by McCreery is another method for studying intermediates in the diffusion layer [71–75]. A laser beam is directed in a parallel direction through the diffusion layer of the electrode and the light is then magnified and focused on a diode-array detector. With this method, spatial resolution of the diffusion layer of 1.25 μm is achieved, and concentration profiles in the diffusion layer are mapped. A detailed description of mass transport processes as well as the kinetics and spectra of intermediates can be obtained. Diffusion coefficients and extinction coefficients for, for example, the benzophenone radical anion were measured with this technique [74, 75].

OTTLE–EPR

The use of EPR as detection mode can be a very powerful tool for the identification of radical intermediates that are electrochemically generated. Different types of electrochemical cells have been developed for that purpose. An OTTLE flat cell with an internal width of only 0.35 mm was used by McQuillan et al. for recording both UV and EPR spectra [76]. The reference and the counter electrode were placed relatively far from the platinum net working electrode; this resulted in a large resistance and made the control of the potential difficult. Such a cell is best suited for studies in highly conducting solvents such as water containing a high electrolyte concentration. McQuillan et al. studied the reduction of anthraquinone sulphonates at high pH, and found that it proceeded by a two-electron process in the presence of the alkali cations Li^+ and Na^+ , but by two one-electron reductions in the presence of tetraalkylammonium cations. It was possible to record the EPR and UV spectra of the radical anion and the UV spectrum of the dianion.

An alternative cell design developed by Allan Bond and shown in Figure 29 is now commercially available from Micro Glass Instruments [77]. The electrochemical cell built into a quartz tube of only 4 mm in outer diameter fits directly into the cavity of the EPR spectrometer. The working electrode is a curled platinum wire, while a 70- μm platinum wire electrocoated with Ag and with the outer layer further converted to AgCl by oxidation serves as a pseudo reference electrode. The advantage of this design is that the two electrodes can be placed close to each other, improving the electrochemical properties of the cell with respect to a lowering of the resistance and time constant. However, this cell is less efficient than the flat OTTLE in the electrochemical generation process because of the smaller dimensions. None of the cells can be used for quantitative investigations of kinetic and mechanistic aspects, as the EPR signal is not proportional to the charge injected into the cells. Neudeck recently proposed a modified design using a flat OTTLE with a laminated gold micromesh [63]. The exposed area of the working electrode is small (1 \times 3 mm) and can be placed completely within the EPR cavity. The connection wire to the working electrode is, furthermore, shielded because of the lamination and does not contribute to the generation of radicals.

The cells described above are all characterized by the working electrode being placed directly in a static solution in the EPR cavity. In general, exhaustive electrolysis is accomplished within 30 s, depending on the exact thickness of the cell, so

Figure 29. The small volume in situ ESR electrochemical cell shown was developed by Allan Bond and is now commercially available from Micro Glass Instruments. From D. A. Fiedler, M. Koppenol, and A. M. Bond, *J. Electrochem. Soc.* 142:862 (1995) [77].

very unstable radicals cannot be detected. A flow-through cell designed by Compton is supposed to combine the best from the flow cell and OTTLE [78]. Essentially, the cell is a dismountable channel electrode with dimensions of $0.4 \times 6 \times 30$ mm, and with applicable flow rates between 10^{-4} and 10^{-1} mL s $^{-1}$. Since the flow is laminar, a parabolic velocity profile will develop across the channel. The sensitivity of the cell is good and kinetic and mechanistic parameters may be deduced from changes occurring as a consequence of variations in the flow rates.

Charge-transfer processes occurring across the liquid–liquid interface have also been studied by EPR. The Galvani potential difference between the two immiscible solvents, water and 1,2-dichloroethane (DCE), was controlled electrochemically by means of a bipotentiostat. The water phase contained potassium ferrocyanide, which, in the DCE phase, by electrochemical polarization of the interface, can reduce a compound such as tetracyanoquinodimethane to its radical anion or oxidize a compound such as tetrathiafulvalene to its cation radical. Both radicals were detected by EPR spectroscopy [79].

OTTLE-IR

The combination of IR spectroscopy with OTTLE cells has not found as many applications as OTTLE-UV, in spite of the much better structural characterization of solution species by IR spectroscopy. OTTLE-IR suffers from the disadvantage that the extinction coefficients in the IR range are much smaller than in the UV range; this means that higher substrate concentrations are required and/or substrates with particularly strong bands need to be chosen for a high signal to noise ratio. In recent years, a number of OTTLE-IR cells have been designed for the study of, in particular, organometallic and inorganic complexes. A simple transmission IR cell can be constructed as shown in Figure 30, with a gold minigrid working electrode sandwiched between two IR transparent windows. The difficult part consists of sealing the cell properly, because normal IR windows made of NaCl or KBr are quite fragile and cannot tolerate large pressures. Polished silicon windows might be used, but unfortunately these will block some wavelength ranges of the IR light. The electrolysis time has to be long (>30 s) for a good signal to noise ratio for the weak IR absorbances.

Another kind of cell, made by Graham and Curran, was based on an internal reflection crystal [80]. A gold minigrid was mounted directly on a prism ($9 \times 9 \times 45$ mm) and on top of this was a zinc selenide prism. The distance (observation) between the minigrid and the prism is typically 13–15 μm , which results in a very short response time. For a potential-step experiment, maximum absorbance is achieved within a couple of seconds. The cell is especially well-suited for potential-scan experiments because the intermediate generated at the electrode will rapidly fill out most of the observation distance even when moderately fast sweep rates (50 mV s $^{-1}$) are applied. Some “memory” effect is, however, present, because the diffusion layer will not be completely evolved on this timescale. At smaller sweep rates (2 mV s $^{-1}$) all of the observation layer behaves like a thin layer, where the concentrations are in equilibrium with the electrode surface concentrations. The cell has been used to study the reduction process of $\text{Fe}(\text{CO})_5$ by CV, where it was pos-

sible to identify most of the intermediates by IR, although the mechanism assigned for the dimerization was not correct [81].

OTTLE-UV (OTTLE/Nernst method)

The design and applications of OTTLE-UV cells have been discussed in details elsewhere [70], and only one important application will be discussed here, namely the construction of a Nernst plot for the determination of the formal reduction potential, $E_O^{\circ'}$, and the electron stoichiometry, n . The ratio of the surface concentrations for a given redox pair O/R can be controlled by the applied electrode potential according to the Nernst equation shown in Eq. 109. (In principle, this equation is more explicit than Eq. 1, since the formal potential incorporates the relevant activity coefficients. For most applications, however, this has no significance.) For a reversible redox pair, the adjustment of the surface concentrations occurs instantaneously whereas in the quasi-reversible case, this process might take a longer time. For some irreversible redox pairs the establishment of the equilibrium is so slow that it is not attained even after several days or years. In a thin-layer cell with its small dimensions, the ratio of concentration becomes the same everywhere in the cell within a few seconds as long as the redox pair is not involved in homogeneous reactions.

The concentration ratio of O and R can be determined by UV spectroscopy at any time by measurement of the absorbance at a wavelength where O and R absorb with different extinction coefficients. A common situation is that one of the two

species is colored with a unique absorbance in the visual range, since either O or R contains an uneven number of electrons. This provides easy access to the determination of, say, C_R , and C_O can then be calculated as $C_O = C_O^* - C_R$, where C_O^* is the initial concentration. In a typical experiment, the applied potential is changed in steps from a situation where C_O/C_R is greater than 1000 to less than 0.001 with special attention paid to the turnover range around one. At each value of the electrode potential, the OTTLE is allowed to equilibrate until no more changes are observed in the UV spectra and the current measured is zero. The latter point is important, because one of the major problems associated with OTTLE, the iR loss, may then be neglected.

The logarithm of the measured C_O/C_R ratios is plotted against the applied electrode potential in a Nernst plot, as illustrated in Figure 31. As predicted by the rearranged Nernst equation given in Eq. 110, the formal potential is then equal to the electrode potential ($E = E_O^{\circ'}$) when $\log(C_O/C_R)$ is zero and the number of electrons consumed n is obtained from the slope which is $nF/2.3RT$.

$$E = E_O^{\circ'} + \frac{RT}{nF} \ln \left(\frac{C_O(x=0)}{C_R(x=0)} \right) \quad (109)$$

$$\log \frac{C_O(x=0)}{C_R(x=0)} = \log \frac{C_O}{C_R} = \left(\frac{nF}{2.3RT} \right) (E - E_O^{\circ'}) \quad (110)$$

In this manner, it is possible to measure $E_O^{\circ'}$ with a precision of a few mV or better. Although $E_O^{\circ'}$ might be determined more easily and with a similar precision for a reversible system by the CV technique, the OTTLE/Nernst experiment is very useful for the study of quasi-reversible systems. The presence of slow heterogeneous kinetics means that the equilibrium is attained relatively slowly upon changing the potential, but this presents no problem as long as the redox pair is kinetically stable. The technique has therefore been used in the measurement of $E_O^{\circ'}$ and n for a large number of inorganic salts and enzymes [70, 82].

When the heterogeneous electron-transfer process at the electrode becomes slow and irreversible, the use of the direct OTTLE/Nernst experiment is inconvenient because of the uncertainties associated with a slow equilibration process. A mediated OTTLE/Nernst experiment should rather be considered, where a redox mediator M_{ox}/M_{red} characterized by a high heterogeneous rate constant is added to the cell (Eq. 111). The concentration ratio of the mediator couple will be adjusted quickly to the applied electrode potential E and, furthermore, it will be in a redox equilibrium (Eq. 112) with the redox pair O/R in the bulk solution, according to Eq. 113.

$$E = E_M^{\circ'} + \frac{RT}{nF} \ln \left(\frac{[M_{ox}]}{[M_{red}]}} \right) = E_O^{\circ'} + \frac{RT}{nF} \ln \left(\frac{[O]}{[R]} \right) \quad (113)$$

Figure 31. OTTLE spectropotentiostatic experiment on 0.87 mM $[\text{Tc}^{\text{III}}(\text{diars})_2\text{Cl}_2]^+$, 0.6 M TEAP in DMF. a) Spectra recorded during applied potentials, mV vs SSCE: A, -250; B, -150; C, -100; D, -75; E, -50; F, 25; G, 100; H, 250. From R. W. Hurst, W. R. Heineman, and E. Deutsch, *Inorg. Chem.* 20:3298 (1981) [82]; b) Plotted data from Figure 31(a), recorded at 403 nm. From W. R. Heineman, F. M. Hawkridge, and H. N. Blount, in *Electroanalytical Chemistry*, Vol. 13 (A. J. Bard, Ed.), Marcel Dekker, New York, 1984, p. 20 [70].

Again, the value of $E_O^{\circ'}$ may be extracted from a Nernst plot of the logarithm of the concentration ratio $[O]/[R]$ against E . In some cases, the measurements are made difficult by the presence of additional absorbances in the UV range due to the mediator couple.

The mediated OTTLE/Nernst method, with 2,6-dichlorophenolindophenol as mediator, was employed by Heineman *et al.* in the measurement of $E_O^{\circ'}$ for cytochrome c [83]. For enzymes, the mediated OTTLE/Nernst method is probably the method of choice, since the heterogeneous charge-transfer processes often are very slow; the electroactive metal center is insulated by the surrounding protein structure and cannot get close to the electrode surface.

2.6.3 Type 3

Fiber-optic probes for UV- and IR spectroelectrochemistry

Fiber-optic probes are now commercially available for transmission UV spectroscopy and, since recently, also for IR spectroscopy. In both cases a bifurcated cable carries the light from the source to the tip of a probe. The tip is constructed so the solution under study can freely flow through entry holes into the light path. The light is reflected at a mounted mirror and passes through the solution once more before it enters another cable that carries the attenuated light to the spectrometer.

The cuvette length is equal to the sum of the light paths to and from the mirror through the solution. The cuvette length is fixed on some probes, but can be adjusted on other probes if the mirror is moved. A commercially available solution transmission probe from Ocean Optics is shown in Figure 32. The fiber-optic probes can be inserted into the solution of an H-cell used for preparative electrolysis, which allows the recording of spectra during the progress of the electrolysis. This provides important information about the nature of the intermediates/products involved as well as about the kinetics.

2.7 Indirect Electrolysis

In the middle of the 1970s a revival of the use of indirect electrolysis in organic chemistry occurred; this was stimulated, in particular, by its advantages in lowering energy consumption and by its ability to enhance product selectivity. A number of papers published by Lund *et al.* [84–86] and Savéant *et al.* [87–89] in this period dealt with both the synthetic possibilities and the kinetics involved, especially concerning the reduction of aromatic and aliphatic halides by radical anions of aromatic and heteroaromatic compounds. In this chapter we will provide a general description of indirect reduction processes; the main emphasis will be on the principles underlying the methodology. Obviously, these principles are also directly applicable to oxidation processes. Next, we present a couple of specific examples

Figure 32. UV dip probe based on light guides, from Ocean Optics.

illustrating the sort of quantitative information that can be extracted by the indirect approach. A wealth of other examples that show the general scope of the methodology can be found in accounts and review articles already available in the literature [90–97].

A direct reduction process involves three main steps, where the substrate first diffuses to the electrode, an electron is transferred from the surface of the electrode, and the substrate then finally returns to the solution in its reduced form. If the electron-transfer process is accompanied by large structural changes in the substrate and/or substantial solvent reorganization, then k^o will be small and the electrode process will be sluggish and become the rate-controlling step. In that case, the only way to increase the reduction rate according to the current–overpotential equation (Eq. 12) is to apply a higher overpotential, although the expense might be a falling current yield due to background discharge or other unwanted side reactions.

In comparison, an indirect electrochemical reduction is based on the steps shown in Figure 33. Here, the electrode transfers an electron to a suitable mediator that diffuses into the solution and transfers the electron to the substrate. The mediator is regenerated and can diffuse back to the electrode surface for another activation cycle. The indirect approach thus combines heterogeneous electron transfer with a homogeneous redox reaction. The mediator therefore acts as an efficient three-dimensional electrode with substantial overall rate enhancement for the reduction

Figure 33. The principle of indirect electrolysis exemplified by a reduction process (see Eqs. 114–119 for a description of the species involved).

process to follow. In most cases this is a great advantage, since the overpotential required for carrying out the reduction of the substrate may be lowered by several hundred mV compared with the direct approach. Moreover, the lowering of the potential is usually accompanied by a gain in the selectivity of the reaction as the selectivity is dependent on the potential differences between the mediator and the various electrophores (functional groups) in the substrate. For a corresponding direct reduction process in which a high overpotential (brute force) is required, such a selective reduction cannot be obtained, in particular, if the reducibility of the different electrophores is alike. Even if the substrate contains only one electrophore, large differences may be observed in the product distributions. The rather negative potentials employed in the direct reduction process often favor the formation of anions due to further reduction of the intermediates formed in the first step; this reaction pathway is less likely in the indirect method.

The mediator is a key species in the indirect reduction (or oxidation) process as it is involved in both the homogeneous and heterogeneous reactions. The most common mediators used are inorganic ions, metal complexes, and aromatic compounds. In general, the following conditions should be fulfilled:

- a) The mediator is more easily reducible than the substrate (for a reduction process)
- b) The heterogeneous rate constant k° is high, so the heterogeneous charge transfer process at the electrode surface is fast.
- c) The homogeneous reaction taking place between the reduced (or the oxidized) form of the mediator and the substrate is fast. Electron-transfer processes are accelerated if they have inner-sphere character.
- d) Both the oxidized and reduced forms of the mediator are characterized by high chemical stability if no substrate is present.
- e) Both the oxidized and reduced forms of the mediator are sufficiently soluble in the chosen solvent. Should problems regarding solubility arise, the use of two-phase systems may be a possibility.

The indirect reduction of many organic substrates, in particular alkyl and aryl halides, by means of radical anions of aromatic and heteroaromatic compounds has been the subject of numerous papers over the last 25 years [98–121]. Many issues have been addressed, ranging from the exploration of synthetic aspects to quantitative descriptions of the kinetics involved. Savéant *et al.* coined the expression “redox catalysis” for an indirect reduction, in which the homogeneous reaction is a pure electron-transfer reaction with no chemical modification of the mediator (i.e., no ligand transfer, hydrogen abstraction, or hydride shift reactions). In the following we will consider such reactions and derive the relevant kinetic equations to show the kind of kinetic information that can be extracted.

The indirect reduction of many organic substrates by radical anions can be described by the following general reaction scheme:

The mediator A denotes a stable aromatic or heteroaromatic compound selected so its standard potential, E_A° , is positive relative to the standard potential of the substrate RX, E_{RX}° . The radical anion $A^{\bullet -}$ is generated by heterogeneous electron transfer (Eq. 114) to A at the electrode surface. The actual indirect reduction process between $A^{\bullet -}$ and RX takes place in a homogeneous step (Eq. 115) with rate constant k_{ET} . The radical anion of the substrate, $RX^{\bullet -}$, formed by this process, cleaves to the radical R^{\bullet} and the anion X^- in a fragmentation reaction (Eq. 116), which may be followed by a number of fast follow-up processes, depending on the nature of R^{\bullet} . For aryl radicals, hydrogen abstraction from the solvent HS as shown in the reaction of Eq. 117 is a potential reaction path. However, regardless of whether R^{\bullet} , a solvent-derived radical S^{\bullet} , or a mixture of them are formed in solution, their fate is determined by $A^{\bullet -}$ as indicated by the processes in Eqs. 118 and 119 [122]. Dimerization or cross-coupling reactions of R^{\bullet} and S^{\bullet} are normally not seen, owing to their low steady-state concentrations which arise because the forward electron-transfer reaction (Eq. 115) is normally the slowest and rate-controlling step. Overall, two molecules of $A^{\bullet -}$ are thus used in the reduction of one molecule of RX.

One of the interesting features of the above scheme is the presence of a competition between the first-order cleavage reaction (Eq. 116) and the second-order reverse electron-transfer process (Eq. 115). According to the overall reaction scheme, neglecting for a while the heterogeneous process (Eq. 114), the differential equation

for species $A^{\cdot-}$ can be expressed as shown in Eq. 120, where the steady-state assumption has been imposed on the intermediates $RX^{\cdot-}$, R^{\cdot} , and S^{\cdot} .

$$\frac{\partial C_{A^{\cdot-}}}{\partial t} = -\beta C_{A^{\cdot-}}, \quad \text{where } \beta = \frac{2k_c k_{ET} C_{RX}}{k_c + k_{-ET} C_A} \quad (120)$$

The competition between the cleavage reaction (Eq. 116) and the reverse electron-transfer reaction (Eq. 115), as expressed by the two terms in the denominator of the above expression, is dependent on the concentration of A, unless $k_c \gg k_{-ET} C_A$. In that case, the rate-controlling step is the forward electron-transfer process (Eq. 114) with $\beta = 2k_{ET} C_{RX}$. If $k_c \approx k_{-ET} C_A$, the reaction kinetics of $A^{\cdot-}$ becomes slower as C_A is increased, and, ultimately, the cleavage reaction is the rate-controlling step with Eq. 115 acting as a pre-equilibrium process, that is, $\beta = \frac{2k_c k_{ET} C_{RX}}{k_{-ET} C_A}$.

The fact that the competition ratio is dependent on C_A can be exploited for the determination of the rate constant k_c , but two main points have to be fulfilled. First of all, the two rate constants involved, k_c and k_{-ET} , should be of such a relative magnitude that a variation of C_A in the range accessible is actually reflected in an effect on the competition ratio of the two reactions. Secondly, if the absolute value of the rate constant k_c is to be calculated from the value of k_{-ET} , then the latter has to be known. This is the case when the reverse electron transfer is so exoergic that it is controlled by the diffusion together of the two species, and k_{-ET} can be set equal to the diffusion-controlled rate constant k_d . The rate constant k_d depends on the viscosity of the specific solvent used, but in most cases it is close to a value of $10^{10} \text{ M}^{-1} \text{ s}^{-1}$. (It should always be checked that the reaction under investigation is controlled by diffusion of the reverse process, i.e., that the rate constant k_{ET} in a plot of $\log k_{ET}$ against the driving force (proportional to $-FE_A^\circ$) is positioned in the region characterized by a slope of $1/59 \text{ mV}^{-1}$ (see below)).

Savéant and coworkers [87–89, 123–125] introduced this approach for determining k_c in linear sweep voltammetry. The experimental voltammograms were compared with simulations to determine cleavage rate constants for radical anions ranging from 10^6 to $5 \times 10^8 \text{ s}^{-1}$. The indirect approach is therefore a very useful supplement to direct techniques such as cyclic voltammetry [126–130], pulse radiolysis [131–135], and flash photolysis [136], which have proven to be convenient and effective tools when the cleavage rate constant of $RX^{\cdot-}$ is lower than 10^7 s^{-1} .

One example illustrating the indirect LSV approach pertains to the reduction of 1-chloronaphthalene with 4-methoxybenzophenone as mediator in DMSO. The experimental parameter measured in the LSV experiments is $i_p/2\zeta i_{pd}$, where ζ is the excess factor, that is, the concentration ratio of the substrate 1-chloronaphthalene and the redox catalyst 4-methoxybenzophenone, and i_p and i_{pd} are the peak currents measured for the mediator with and without the substrate being present. Note that the currents obtained are dependent on the nature of the products formed in Eqs. 118 and 119, that is, the amount of A regenerated. In many situations a reduction process is expected to dominate, but a contribution from other processes has to be looked for and specifically taken into account in the simulation procedure. In the present example, the forward electron-transfer reaction (Eq. 114) is rate-controlling

Figure 34. Reduction of 1-chloronaphthalene in DMSO as catalyzed by 4-methoxybenzophenone. Mixed kinetic control, the excess factor, ζ (denoted by γ in the plot) = 0.5, $\nu = 0.1 \text{ V s}^{-1}$, $C_A = 0.02 \text{ M}$. The abscissa $\log \lambda / \lambda_2$ corresponds to $\log k_c / k_{-ET} C_A$. Working curve for $\lambda_1 = RTk_{ET} C_A / F\nu = 0.5$. From C. P. Andrieux, C. Blocman, J. M. Dumas-Bouchiat, F. M'Halla, and J.-M. Savéant, *J. Am. Chem. Soc.* 102:3806 (1980).

for $C_A < 4 \times 10^{-3} \text{ M}$; this allows straightforward determination of k_{ET} to be $100 \text{ M}^{-1} \text{ s}^{-1}$. On the other hand, a C_A value of above $4 \times 10^{-3} \text{ M}$ shifts the system into the region of mixed kinetic control. The ratio k_c / k_{-ET} can then be determined to be 10^{-2} M by comparison of the experimental value of $i_p / 2\zeta i_{pd}$ obtained at $\nu = 0.1 \text{ V s}^{-1}$, $\zeta = 0.5$, and $C_A = 0.02 \text{ M}$ with the corresponding working curve of $i_p / 2\zeta i_{pd}$ vs $\log(k_c / k_{-ET} C_A)$, as shown in Figure 34. With $k_{-ET} = k_d = 5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, $k_c = 5 \times 10^7 \text{ s}^{-1}$.

In LSV, the upper limit of measurable k_c of $5 \times 10^8 \text{ s}^{-1}$ is set by the maximum C_A of about 20 mM which is tolerated without introducing migration of $A^{\cdot-}$ when the concentration of the supporting electrolyte is 0.1 M. Other techniques, however, may not have this limitation, and this would allow the range of accessible k_c values to be extended as a matter of course. Recently, we described an electrochemical method employing the RDE technique that extends the upper limit of accessible rate constants to ca. $5 \times 10^9 \text{ s}^{-1}$ [141]. The method is based on steady-state current measurements of $A^{\cdot-}$, but other techniques, such as optical detection of $A^{\cdot-}$, could also be considered. First, $A^{\cdot-}$ is generated electrochemically to a given concentration (ca. 1 mM), followed by the actual experiment where the decay in the concentration of $A^{\cdot-}$ due to the reaction with RX is recorded as a function of time for varying concentrations of RX and A. In this procedure, there is no restrictions imposed by migration on the maximum value of C_A applicable, as long as the amount of $A^{\cdot-}$ generated initially is kept low.

Figure 35. The parameter

$\gamma = \frac{\beta}{2C_{RX}}$ plotted against the concentration of the mediator 2,3-dimethylnaphthoquinone, C_A . The parameter β is the decay constant of the reaction between $A^{\cdot-}$ and diphenyl disulfide [141].

From decay kinetics, the parameter β can be obtained by Eq. 120. For the sake of convenience, the parameter γ defined in Eq. 121 is introduced.

$$\gamma = \frac{\beta}{2C_{RX}} = \frac{k_c k_{ET}}{k_c + k_{-ET} C_A} = \frac{k_{ET}}{1 + \frac{k_{-ET} C_A}{k_c}} \quad (121)$$

Thus, measurement of γ at different concentrations of mediator A will allow the parameters k_{ET} and the ratio k_c/k_{-ET} to be obtained directly in a nonlinear least-square fit of the values to Eq. 121. Alternatively the parameters may be obtained in a linear fit of $1/\gamma$ against C_A ; the intercept at the ordinate provides $1/k_{ET}$ and the slope is given by $k_{-ET}/k_c k_{ET}$. An example of this procedure is the determination of k_c for the radical anion of diphenyl disulfide, where values of γ were measured for different values of C_A , where A is 2,3-dimethylnaphthoquinone. In Figure 35, a plot of γ vs C_A is shown, where the nonlinear fit leads to the following values: $k_{ET} = 0.1 \text{ M}^{-1} \text{ s}^{-1}$ and $k_c/k_{-ET} = 0.05 \text{ M}$ (i.e., $k_c = 5 \times 10^8 \text{ s}^{-1}$ with $k_{-ET} = 10^{10} \text{ M}^{-1} \text{ s}^{-1}$).

Besides the possibility of extracting cleavage rate constants k_c for short-lived radical anions $RX^{\cdot-}$, the redox catalysis approach may also provide the standard potential of RX , E_{RX}° , from the measurements of k_{ET} . In practice, the rate constants k_{ET} are obtained for the reaction between a number of aromatic radical anions with different values of E_A° and a given substrate by means of CV, LSV, or a potentiostatic technique employing an ultramicroelectrode or RDE. According to the theoretical treatment of the above kinetic scheme, the rate constant k_{ET} can be expressed as shown in Eq. 122 [125].

$$\frac{1}{k_{ET}} = \frac{1}{k_d} + \frac{1}{k_{ET}^\circ \exp[(\alpha_{hom} F/RT)(E_{RX}^\circ - E_A^\circ)]} + \left(\frac{1}{k_d} + \frac{1}{Z_{hom}} \right) \frac{1}{\exp[(F/RT)(E_{RX}^\circ - E_A^\circ)]} \quad (122)$$

Figure 36. The dependency of the homogeneous electron-transfer rate constant, k_{ET} on the potential difference, $E_{RX}^o - E_A^o$. In the logarithmic plot, three asymptotes are noted, with slopes of 0, $-1/118 \text{ mV}^{-1}$, and $-1/59 \text{ mV}^{-1}$, representing diffusion-controlled, activation-controlled, and counter-diffusion-controlled electron-transfer reactions, respectively [125]. The transfer coefficient α_{hom} is set equal to 0.5.

The parameter Z_{hom} is the collision frequency ($= 3 \times 10^{11} \text{ M}^{-1} \text{ s}^{-1}$), k_{ET}^o is the homogeneous standard rate constant and α_{hom} is the homogeneous transfer coefficient. Depending on the magnitude of the three terms given in Eq. 122, a diagram of $\log k_{ET}$ vs E_A^o , as shown in Figure 36 can be broken down into three regions, namely from left the diffusion-controlled, the activation-controlled, and the counter-diffusion-controlled zone with $k_{-ET} = k_d$. The E_{RX}^o value can therefore be obtained from the plot by simple extension of a line of slope $-1/59 \text{ mV}^{-1}$ (the dashed line in Figure 36) from the counter-diffusion controlled zone to the diffusion-controlled limit, that is, the standard potential is calculated on the basis of the last term of Eq. 122. If $Z_{hom} \gg k_d$, $1/Z_{hom}$ can be neglected and the last term can be rewritten as shown in Eq. 123.

$$k_{ET} = k_d \exp[F/RT(E_{RX}^o - E_A^o)] \quad (123)$$

Note that the above analysis only applies if the cleavage process (Eq. 116) occurs completely outside the molecular diffusion layer. Should the cleavage process pro-

ceed faster ($k_c > 10^9 \text{ s}^{-1}$), an error of ca. 100 mV might be introduced in the determination of E_{RX}^0 . Detailed analyses of this problem have been offered elsewhere [125].

3 Radiation-Chemical Techniques

George V. Buxton and Quinto G. Mulazzani

3.1 Introduction

Radiation chemistry is defined here as the chemistry ensuing from the interaction of high-energy photons and particles with matter, so-called ionizing radiation. Although the energy required to ionize a molecule is typically of the order of 10 eV, the penetration depth in the condensed phase of particles with such energy is very small. In practice, the types of radiation commonly used for general chemistry are ^{60}Co γ -rays or fast electrons from an accelerator with energies typically in the range 2–20 MeV. In each case the result of the interaction is the ejection of a single electron, which may have sufficient energy to effect ionization of further molecules, but which eventually becomes thermalized and trapped in the liquid or solid medium. In this way, stable molecules (M) are converted into highly reactive free radicals ($\text{M}^{\bullet+}$) and solvated electrons (e_s^-):

A distinguishing feature of radiation chemistry is the nonselective absorption of energy so that the molecules are ionized according to their relative abundance in the medium of interest. For example, in dilute solution ($\leq 0.1 \text{ mol dm}^{-3}$) the ionized molecules (M) are effectively those of the solvent so that a knowledge of the radiation chemistry of the solvent is of paramount importance for most studies using radiation-chemical methods.

Examples of the chemical fate of the reactants generated radiolytically in specific media are described in this chapter and, as one would expect, in many cases the reactions involve the gain or loss of a single electron. This is always true for the solvated electron which can only react by transfer into a vacant orbital of an acceptor:

In many cases the product S^- is itself a free radical ($S^{\bullet-}$), or a hyper-reduced metal ion, which in turn reacts in one-electron gain or loss processes. It is not surprising, then, that radiation-chemical methods are widely used in the study of electron-transfer processes. Of particular value is the technique of pulse radiolysis which permits reactions to be studied on timescales ranging from seconds down to picoseconds, so that even the most reactive species can be studied. It is this technique and its applications that form the subject matter of this chapter which begins with an outline of the radiation chemistry of water and other solvents. Next there is a historical view of pulse radiolysis, some of the landmark discoveries are discussed, followed by a description of the principal features of a pulse radiolysis facility and the various methods of detecting and measuring transient species. The chapter ends with some examples of data capture and analysis, and methods of sample preparation.

3.2 Interaction of Ionizing Radiation with Condensed Matter

The radiation chemistry of liquids and solids is distinguished by the nature of the energy loss suffered by the ionizing particle along its track through the medium [1]. The rate of energy loss per unit length of the track is referred to as the linear energy transfer or stopping power or, more commonly, LET. When the ionizing particle is a high-energy electron, the ionization events occur in small clusters, called spurs, that are widely separated along the track of the primary particle, and the radiation is said to be of low LET. When the particle is an energetic nuclear ion such as H^+ , He^{2+} , and so forth, the rate of energy loss is much higher; the spurs are more closely spaced and can overlap to form cylindrical columns of ionized molecules. In this case, the radiation has a high LET; the two types of radiation are compared in Figure 1. In reality, there are high LET segments in the track of an electron because the LET increases as the energy of the electron decreases, as shown in Figure 1. Thus, some of the low-energy electrons produced in the initial ionizations have sufficient energy to cause further ionizations in close proximity, forming spurs. Similarly, there are relatively low LET segments in the track of an ion with high LET caused by the ejected electrons that have sufficient energy to form their own (branch) tracks. Thus, LET actually varies along the track of the particle, but it is often sufficient just to consider LET in terms of the total energy lost by the particle divided by the length of the track. The descriptions that follow of the radiolysis of water and other solvents is for low LET radiation because almost invariably fast electrons from accelerators or ^{60}Co γ -rays, which themselves generate fast electrons by Compton scattering [1], are the sources used for the radiolytic generation of the species whose chemistry is to be studied. As will be described later (Section 3.7.1, under "Sample Cell and Flow System with Optical Detection"), the size of the sample to be irradiated is chosen to ensure that energy deposition in it is fairly uniform.

Figure 1. Stopping power of water as a function of energy of impinging electrons or protons. (Adapted from A.J. Swallow, *Radiation Chemistry*, Longman, London, 1973, p. 28).

3.3 The Radiation Chemistry of Water

The sequence of events resulting from the interaction of low LET radiation with water is summarized by the following reactions (the time by which the event is estimated to be complete is also given):

The reaction given in Eq. 3 represents ionization and electronic excitation of water molecules; this occurs on the timescale of an electronic transition. The positive radical ion H_2O^{*+} is known to undergo the ion-molecule reaction (Eq. 4) in the gas phase with a rate constant of $8 \times 10^{12} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ [2], which sets the lifetime of the ion at less than 10^{-14} s in the liquid. The electronically excited states H_2O^* are known to dissociate in the gas phase, as shown in Eq. 5, and the electron released in the ionization event is known to become thermalized and solvated in less than

10^{-12} s [3]. It is generally accepted that at about 10^{-12} s after ionization the products of Eqs. 4–6 are in thermal equilibrium with the bulk liquid and are clustered together in spurs. Next, these products begin to diffuse randomly, with the result that a fraction of them encounter one another and react together to form molecular or secondary radical products, while the remainder escape into the bulk liquid and effectively become homogeneously distributed throughout the medium. This spur expansion and reaction is complete by about 10^{-7} s, at which time the radiolysis of water can be represented by reaction (7) [4]:

where the numbers are the radiation chemical yields (G values) in units of $\mu\text{mol J}^{-1}$. In the early literature the G values are quoted as molecules/100 eV, and some authors still use these units today. The conversion factor is as follows:

$$1 \text{ molecule/100 eV} \equiv 1.036 \times 10^{-7} \text{ mol J}^{-1} \text{ (or } 0.1036 \mu\text{mol J}^{-1}\text{)}$$

Some authors quote G values without including the units, and most commonly the omitted units are molecules/100 eV, so the reader should exercise care in interpreting these numerical values.

The yields of the initial products of Eqs. 4–6 are not yet established unequivocally. The results of attempts to model the early stages of water radiolysis to match up with experimental measurements that are limited to about 10^{-10} s suggest that $G(\text{ions})$ and $G(\text{excitation})$ have values of about 0.5 and 0.1 $\mu\text{mol J}^{-1}$, respectively [5]. Thus, around 40 % of the initial yields are consumed by the spur reactions. The spur reactions are listed in Table 1.

Table 1. Spur reactions in water.

Reactions	$k [10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}]^a$
$e_{\text{aq}}^- + e_{\text{aq}}^- \rightarrow \text{H}_2 + 2\text{OH}^-$	0.55
$e_{\text{aq}}^- + \cdot\text{OH} \rightarrow \text{OH}^-$	3.0
$e_{\text{aq}}^- + \text{H}_3\text{O}^+ \rightarrow \text{H}^\bullet + \text{H}_2\text{O}$	2.3
$e_{\text{aq}}^- + \text{H}^\bullet \rightarrow \text{H}_2 + \text{OH}^-$	2.5
$e_{\text{aq}}^- + \text{H}_2\text{O}_2 \rightarrow \cdot\text{OH} + \text{OH}^-$	1.1
$\text{H}^\bullet + \text{H}^\bullet \rightarrow \text{H}_2$	0.5
$\cdot\text{OH} + \cdot\text{OH} \rightarrow \text{H}_2\text{O}_2$	0.55
$\cdot\text{OH} + \text{H}^\bullet \rightarrow \text{H}_2\text{O}$	0.7
$\text{H}_3\text{O}^+ + \text{OH}^- \rightarrow 2\text{H}_2\text{O}$	14.0 ^b

^a Values taken from Ref. [7]. ^b K.J. Laidler, *Chemical Kinetics*, McGraw-Hill, New York, 1965, p. 535.

[66b]. ^f($^{\bullet}OH + e^- \rightarrow OH^-$). ^g($^{\bullet}OH + e^- + H^+ \rightarrow H_2O$). ^h($H + H_2O \rightarrow e_{aq}^- + H_3O^+$). ⁱ($^{\bullet}OH + H_2O \rightarrow O^{\bullet -} + H_3O^+$).

3.3.1 Properties of the Primary Radicals

The physical properties of significance here are summarized in Table 2. The hydrated electron and the hydrogen atom are strong reducing agents and the hydroxyl radical is a powerful oxidant. Because of these properties, they are very effective in bringing about one-electron changes in molecules and ions.

The hydrated electron

The hydrated electron may be visualized as a localized electron surrounded by oriented water molecules. As mentioned earlier, it reacts by adding into a vacant orbital on the acceptor molecule or ion (Eq. 2). Rate constants for this reaction range from $19 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ for $S = H_2O$ up to the diffusion-controlled limit, but the activation energy is invariably small ($6\text{--}30 \text{ kJ mol}^{-1}$); this indicates that the entropy of activation is the dominant kinetic parameter. This can be understood in terms of the accessibility to the electron of a vacant orbital on S. Molecules such as water, simple alcohols, ethers, and amines have no low-lying empty orbitals to accommodate an extra electron; this explains why solvated electrons have an appreciable lifetime in these solvents. On the other hand, e_{aq}^- reacts rapidly with organic compounds with low-lying vacant orbitals, for example, most aromatics, halides, aldehydes, ketones, thiols, disulfides, and nitro compounds.

In its reactions, e_{aq}^- acts as a nucleophile. Thus, its reactivity is greatly enhanced by electron-withdrawing groups next to double bonds or on aromatic rings. Although the first step in the reaction is electron addition, this is in some cases followed by rapid dissociation of an anionic fragment so that the overall process can be viewed as one of dissociative capture. This is epitomized by organic halides:

Some characteristic reactivities of e_{aq}^- are illustrated by the data in Table 3. A

Table 3. Rate constants for some reactions of e_{aq}^- .^a

Solute (inorganic)	k [dm ³ mol ⁻¹ s ⁻¹]	Solute (organic)	k [dm ³ mol ⁻¹ s ⁻¹]
O ₂	1.9×10^{10}	(CH ₃) ₂ CO	6.5×10^9
H ₃ O ⁺	2.3×10^{10}	C ₆ H ₆	1.1×10^7
Ag ⁺	3.9×10^{10}	C ₆ H ₅ Cl	6.4×10^8

Fe(CN) ₆ ³⁻	3.1×10^9	C ₂ H ₄	$<3 \times 10^5$
Fe(CN) ₆ ⁴⁻	$<7 \times 10^4$	CH ₂ =CCl ₂	2.3×10^{10}
Co(NH ₃) ₆ ³⁺	8.7×10^{10}	CO ₂	7.7×10^9
H ₂ O	19	C(NO ₂) ₄	5.3×10^{10}

^a Values taken from Ref. [7]. ^b MV²⁺ = 1,1'-dimethyl-4,4'-bipyridinium.

notable feature of these data is the reactivity of e_{aq}^- with Cd²⁺ and CrO₄²⁻ where the rate constants are larger than those predicted by the Debye–Smoluchowski expression for diffusion-controlled reactions between charged reactants. It is suggested [6] that the larger than normal reaction radius for these reactions reflects the quantum-mechanical nature of e_{aq}^- and its ability to tunnel from its solvent trap to the acceptor. Tunnelling between solvent traps may also explain the mobility of e_{aq}^- (see Table 2) because it is much higher than that expected for a monovalent anion of radius 0.3 nm.

The hydrogen atom

The hydrogen atom is not an important primary radical in neutral and alkaline solution, but it is the major reducing radical at low pH where the following reaction (Eq. 9) is rapid:

It is a less powerful reductant than e_{aq}^- (Table 2) and can be considered formally as a weak acid with $pK_a = 9.6$:

although with $k_{3,10} = 2.2 \times 10^7 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ and $k_{-3,10} = 19 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ [7], equilibrium is not established under normal conditions.

The hydrogen atom readily reduces cations with higher reduction potentials than itself, but generally at a slower rate than e_{aq}^- . In some cases it reacts via the for-

mation of a hydride complex and effectively becomes an oxidant:

With many organic compounds it reacts like $\cdot\text{OH}$ (see below), abstracting H from alkyl groups and adding to centers of unsaturation. Because it absorbs only in the far-UV region, many of its rate constants have been measured by competition kinetics [7].

The hydroxyl radical

The hydroxyl radical is a powerful oxidant with a standard reduction potential of 2.73 V in acidic solution. In neutral solution where the free energy of neutralization of OH^- by the proton is not available, the reduction potential is calculated to be 1.9 V (Table 2).

Several inorganic anions and low-valent transition metal ions are readily oxidized by $\cdot\text{OH}$, and the reaction is commonly represented as a one-electron transfer process:

There are, however, a number of examples which show that the reaction actually proceeds via the formation of an adduct, followed by an inner-sphere electron transfer. In the case of halide ions, X^- , the intermediate species $\text{HOX}^{\bullet-}$ have been observed by pulse radiolysis and it has been suggested that this is the reaction path for most oxidizable inorganic anions [8].

Similarly, pulse radiolysis studies of the oxidation of metal ions by $\cdot\text{OH}$ reveal that the reaction can be represented by the following equation:

for $\text{M}^{n+} = \text{Ti}^+, \text{Ag}^+, \text{Cu}^{2+}, \text{Sn}^{2+}, \text{Fe}^{2+}, \text{Mn}^{2+}, \text{Cr}^{3+}$. It has been proposed that $\cdot\text{OH}$ is unlikely to react by simple outer-sphere electron transfer because of the large solvent reorganization energy involved in forming the hydrated hydroxide ion [8], and this does seem to be borne out by the experimental evidence.

The radical $\cdot\text{OH}$ reacts with many inorganic anions at near-diffusion-controlled rates, but with metal ions there seems to be an upper limit of about $3 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$, regardless of the reduction potential of M^{n+} . There is no correlation between the measured values of $k_{3,13}$ and the rates of exchange of water molecules coordinated to M^{n+} , which rules out ligand substitution as a general mechanism; other possibilities are abstraction of H from a coordinated water molecule and $\cdot\text{OH}$ entering the coordination shell to increase the coordination number by one.

At high pH, $\cdot\text{OH}$ is rapidly converted to $\text{O}^{\bullet-}$:

with $k_{3,14} = 1.2 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ and $k_{-3,14} = 9.3 \times 10^7 \text{ s}^{-1}$ [7] and equilib-

rium is rapidly established. $\text{O}^{\bullet-}$ is generally less reactive than $\cdot\text{OH}$ with inorganic anions, and with Br^- , CO_3^{2-} , and $\text{Fe}(\text{CN})_6^{4-}$ the rate is immeasurably slow. This property was used to establish (see below) the value of the equilibrium constant $K_{3,14}$ (Table 2).

In its reactions with organic molecules, $\cdot\text{OH}$ behaves as an electrophile whereas $\text{O}^{\bullet-}$ is a nucleophile. Thus, like H^{\bullet} (see above), $\cdot\text{OH}$ readily adds to double bonds but $\text{O}^{\bullet-}$ does not; however, both forms of the radical abstract H from C–H bonds. In the case of an aromatic molecule carrying an aliphatic side chain, $\cdot\text{OH}$ adds preferentially to the aromatic ring and $\text{O}^{\bullet-}$ abstracts H from the side chain; this can result in a change of reaction mechanism when the pH is raised so that $\text{O}^{\bullet-}$ replaces $\cdot\text{OH}$ as the oxidant.

3.3.2 Generation of Secondary Radicals

Because, as shown by Eq. 7 and Table 2, the radiolysis of water produces approximately equal numbers of powerful reducing (e_{aq}^- , H^{\bullet}) and oxidizing radicals ($\cdot\text{OH}$), for its chemical applications it is desirable to create either totally reducing or totally oxidizing conditions. This is readily achieved by interconversion of the primary radicals, by conversion of the primary radicals into a single kind of secondary radical, or by removal of the unwanted primary radical by reaction to form a relatively inert secondary radical. Some useful systems that satisfy these requirements are described below.

Oxidizing conditions

A most convenient and widely used method of achieving almost totally oxidizing conditions is to saturate the water with N_2O , which converts e_{aq}^- to $\cdot\text{OH}$:

Under these conditions, the concentration of N_2O is $2.5 \times 10^{-2} \text{ mol dm}^{-3}$ and, since $k_{3,15} = 9.1 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ [7], $k_{3,15}[\text{N}_2\text{O}]$ is $2.3 \times 10^8 \text{ s}^{-1}$, so that the radical conversion is essentially complete in about 15 ns. From this it is clear that a pulse radiolysis setup with a time resolution shorter than this is of no advantage when $\cdot\text{OH}$ is generated by this method. It should also be borne in mind that the initial product of reaction (15) is $\text{O}^{\bullet-}$ and that the half-life for its protonation in water is ca. 8 ns.

The available yield of $\cdot\text{OH}$ under these conditions has been shown [9] to fit an empirical equation:

$$G(\cdot\text{OH}) = 0.54 + \frac{0.31(k[S]/\lambda)^{1/2}}{1 + (k[S]/\lambda)^{1/2}} \mu\text{mol J}^{-1} \quad (16)$$

where $\lambda = 4.7 \times 10^8 \text{ s}^{-1}$ and k is the rate constant for the reaction of $\cdot\text{OH}$ with the solute S. The hydrogen atom reacts only slowly with N_2O ($k = 2.1 \times 10^6$

dm³ mol⁻¹ s⁻¹) [7] so that approximately 90 % of the radicals available in N₂O-saturated neutral solution are [•]OH and 10 % are H[•]. At pH > 11, where the reaction of Eq. 10 becomes increasingly important, G([•]OH) can increase up to 0.6 μmol J⁻¹, whereas at pH < 3 the fraction of oxidizing radicals decreases because the reaction of Eq. 9 competes with the reaction of Eq. 15.

The radical [•]OH is rather unselective when it abstracts H from C–H bonds because of the significantly larger energy of the H–OH bond being formed. More selective oxidizing radicals can be obtained by conversion of [•]OH into another inorganic radical, for example: Br₂^{•-}, I₂^{•-}, CO₃^{•-}, N₃[•], and so forth, which have different reduction potentials (see Table 4). This strategy is particularly useful for the study of redox changes in metalloproteins and organometallic complexes, because the secondary inorganic radicals are more likely to react selectively at the metal center, whereas [•]OH will also attack the organic moiety and generate a reducing radical there.

Another convenient method of creating oxidizing conditions is by the following reaction:

This reaction generates the strong oxidant $SO_4^{\bullet-}$, which has a reduction potential of 2.43 V (see Table 4). Thus, it is a more powerful oxidizing radical than $\bullet OH$ in neutral solution and can be used to generate other oxidants such as Cl^\bullet and NO_3^\bullet through electron-transfer reactions with Cl^- and NO_3^- , respectively [7a].

Reducing conditions

A convenient method of obtaining totally reducing conditions is to convert all the primary radicals to the same secondary reducing radical in N_2O -saturated solution containing a suitable organic solute. For example, when the solute is 2-propanol, practically all (see below) of the primary radicals e_{aq}^- , H^\bullet , and $\bullet OH$ are converted to $(CH_3)_2\bullet COH$ by the reactions shown in Eqs. 15, 18, and 19:

Alternatively, when acetone replaces N_2O , Eq. 20 replaces Eq. 15:

and the same result is achieved. Other simple alcohols such as methanol and ethanol are often used as a source of secondary reducing radicals and it is the H on the α -carbon atom that is preferentially abstracted, as shown for 2-propanol. However, $\bullet OH$ does abstract at other positions, so that, in practice, a mixture of radicals is produced where only one is desired. The distributions of radicals formed by reaction of $\bullet OH$ with a variety of simple alcohols are given in Table 5.

Table 5. Abstraction by $\bullet OH$ radicals from various positions in alcohols.^a

Compound	% Abstraction from α C-H	% Abstraction from other C-H	% Abstraction from OH

The alcohol radicals contain a dissociable proton on the hydroxyl group so that the basic form will begin to be present when the pH of the solution approaches the $\text{p}K_a$ of the radical. Generally, the basic form of an alcohol radical is a stronger reductant than the undissociated form. The relevant data are collected in Table 6.

Also included in Table 6 are data for the carboxyl radical which, because of its low $\text{p}K_a$, exists in its basic form even at low pH, and is thus a very effective reductant over the whole pH range, although it is not as powerful as e_{aq}^- . It is generated in the reactions represented by Eqs. 21–23 and, unlike the alcohols, only one kind of radical is produced:

When it is required to have e_{aq}^- as the reducing agent, it is customary to add 2-methyl-2-propanol (tert-butanol) to the solution to convert $\cdot\text{OH}$ to the relatively unreactive radical $\cdot\text{CH}_2(\text{CH}_3)_2\text{COH}$. This system can be exploited to generate hyper-reduced states of metal ions, as in Eq. (24), for example:

The monovalent ions Cd^+ , Co^+ , Ni^+ , and Zn^+ are themselves strong reductants and can be used to reduce metalloproteins at sites where there is negative charge which makes them less accessible to e_{aq}^- .

It is clear from the foregoing information that the radiolysis of water provides a powerful method of generating one-electron redox agents that can be finely tuned in terms of reduction potential and electric charge. The method has been widely

exploited in general chemistry and has generated a wealth of kinetic [7a] and mechanistic information for these redox agents which can be retrieved from the bibliographic database at <http://www.rcdc.nd.edu>.

3.4 The Radiation Chemistry of Organic Liquids

Although the radiation chemistry of organic liquids is generally more complex than that of water, a substantial knowledge of electron-transfer processes in these systems has, nevertheless, been built up. The advantage of organic liquids over water is the range of solvent polarities available so that species that are insoluble in water can be studied by dissolving them in a suitable solvent, or mixture of solvents.

The principal features that distinguish organic liquids from water are the following:

- 1) Organic molecules contain more atoms and bonds than water, therefore the radiolytic products resulting from ionization and fragmentation are more numerous;
- 2) The generally lower relative permittivity of organic liquids means that the coulombic field of the positive ion (see Eq. 1) influences the thermalized electron more strongly, resulting in geminate recombination of the primary ions. A consequence of this is that there is less chance for the ions to react with solutes. Nevertheless, liquids such as simple alcohols, ethers, and ketones are sufficiently polar to solvate a large enough fraction of the thermalized electrons to make them useful media in which to study redox reactions.

For a low LET track, the distance, r_c , at which the potential energy of a separated ion pair is equal to the thermal energy (kT) is given by the Onsager equation [10]:

$$r_c = \frac{e^2}{4\pi\epsilon_0\epsilon_r kT} \quad (25)$$

where r_c is in meter, e is the electronic charge (1.602×10^{-19} C), ϵ_0 is the permittivity of free space (8.854×10^{-12} F m⁻¹), ϵ_r is the relative permittivity (dielectric constant) of the medium, k is the Boltzmann constant (1.381×10^{-23} J K⁻¹), and T is the absolute temperature. Values of r_c for a number of liquids are listed in Table 7. Depending on the value of r_c , a greater or lesser fraction of the ion pairs escape geminate recombination and become free (solvated) ions but, as with water, the free solvated ions may exist in spurs, in which case only a fraction of these free ions would escape into the bulk solution. G values of free ions in various liquids are also included in Table 7. The general trend is that G_{fi} increases as r_c decreases, but there are notable exceptions; the large values of G_{fi} for neopentane and tetramethylsilane reflect the high mobility of the electron in these liquids [10], whilst G_{fi} for ammonia

Table 7. Onsager radii and free ion yields for some liquids.

may be attributable to the slowness of the reaction of e_s^- with NH_4^+ [7a]. Detailed information on the radiolytic behavior of a great variety of organic and other non-aqueous solvents, for example, ammonia, can be found at <http://www.rcdc.nd.edu>.

3.5 One-Electron Reduction and Oxidation in Nonaqueous Solvents

In the following section some pulse radiolysis investigations are described in which the radiolysis of nonaqueous solvents has been used to generate one-electron redox reagents and, in some cases, to characterize their involvement in electron-transfer reactions.

3.5.1 Alcohols

Methanol

The radiolysis of methanol can be represented by Eq. 26:

Both H^\bullet and $\text{CH}_3\text{O}^\bullet$ react rapidly ($t_{1/2} = 18$ ns and 106 ns, respectively) with the solvent to produce additional $^\bullet\text{CH}_2\text{OH}$:

Thus, in argon-purged solution, the main reactive species are the one-electron reductants e_s^- and $^\bullet\text{CH}_2\text{OH}$. In alkaline solution, $^\bullet\text{CH}_2\text{OH}$ deprotonates to form $\text{CH}_2\text{O}^{\bullet-}$, which is a more powerful reductant than $^\bullet\text{CH}_2\text{OH}$ (see Table 6). In acidic solution, or neutral solution saturated with N_2O , e_s^- is converted to $^\bullet\text{CH}_2\text{OH}$ by the reactions of Eqs. 29–31:

Therefore, when the solubility of a compound is higher in methanol than in water, the radiolysis of methanol may provide a more efficient method of effecting one-electron reduction of that compound. Some illustrative examples are given below.

Transition metal complexes

The reduction of transition metals with organic ligands has been the subject of a number of studies in methanol [11]:

- 1) One-electron reduction of the following complexes: $[\text{Co}^{\text{II}}(\text{DPE})_2\text{Br}]\text{Br}$, $[\text{Co}^{\text{II}}(\text{DPE})_2\text{Cl}]\text{ClO}_4$, $[\text{Rh}^{\text{I}}(\text{DPE})_2]\text{Cl}$ or $[\text{Rh}^{\text{I}}(\text{DPE})_2]\text{ClO}_4$, and $[\text{Rh}^{\text{I}}(\text{VPP})_2]\text{Cl}$, where DPE = 1,2-bisdiphenylphosphinoethane and VPP = *cis*-1,2-bisdiphenylphosphinoethylene [11a]. The Co^{II} complexes are reduced by e_s^- , H^\bullet , and $^\bullet\text{CH}_2\text{OH}$ to give $\text{Co}(\text{DPE})_2\text{X}$ which eliminates X^- , giving $\text{Co}(\text{DPE})_2^+$. The reaction of the latter species with H_2 and CO could then be examined. The Rh^{I} complexes were reduced only by e_s^- . The products regenerated the starting compounds, presumably by reacting with CH_3OH ;
- 2) One-electron reduction of a series of hydrido complexes of iron(II)-containing organonitriles of general formula $t\text{-FeH}(\text{L})(\text{DPE})_2^+$, where $\text{L} = \text{CH}_3\text{CN}$, $\text{CH}_3\text{CH}_2\text{CN}$, CH_2CHCN , $\text{C}_6\text{H}_5\text{CN}$, and $p\text{-CH}_3\text{C}_6\text{H}_4\text{CN}$. Reduction results in the loss of L, to give the iron(I) complex $\text{FeH}(\text{DPE})_2$. On the other hand, for $\text{L} = p\text{-ClC}_6\text{H}_4\text{CN}$, reduction by e_s^- causes Cl^- to be eliminated leaving a neutral radical coordinated to the Fe^{II} center [11b]. When $\text{L} = \text{CO}$ or $\text{P}(\text{OCH}_3)_3$, reduction by e_s^- induces ring-opening of the DPE ligand [11c]. Investigations such as these complement electrochemical studies and provide mechanistic and kinetic details that are not otherwise accessible.

Quinones

Quinones, which play an important part in oxidation–reduction processes in nature, have very low solubility in water but their one-electron reduction can be readily investigated in methanol by pulse radiolysis [12]. In this way, the semiquinone radicals of 9,10-anthraquinone [12a] and quinizarin [12b], generated by e_s^- , $\cdot\text{CH}_2\text{OH}$ and $\text{CH}_2\text{O}^{\cdot-}$, have been characterized.

Oxidation in methanol

Although reducing conditions are readily achieved in methanol radiolysis, it is also possible to observe one-electron oxidation. For example, pulse radiolysis of N_2O -saturated solutions of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) or I^- results in the formation of $\text{TMPD}^{\cdot+}$ and $\text{I}_2^{\cdot-}$, respectively. The oxidant was assigned as the methoxy radical $\text{CH}_3\text{O}^{\cdot}$, whose half-life in pure methanol was estimated to be 106 ns [13].

Secondary oxidizing radicals such as $\text{Br}_2^{\cdot-}$ have also been generated in methanol by the reaction of e_s^- with SF_6 [14], where the initial oxidant may be $\cdot\text{SF}_5$. The spectrum of $\cdot\text{SF}_5$ in methanol is reported to have λ_{max} at 300 nm and $\epsilon_{\text{max}} = 130 \text{ m}^2 \text{ mol}^{-1}$ [15]. In the absence of an oxidizable solute, $\cdot\text{SF}_5$ decays by mixed first- and second-order kinetics, which are attributed to its self-reaction and reaction with $\cdot\text{CH}_2\text{OH}$ and CH_3OH .

2-Propanol

The radiation chemistry of 2-propanol is analogous to that of methanol, that is, the main reactive species are e_s^- and $(\text{CH}_3)_2\cdot\text{COH}$. In alkaline solution, $(\text{CH}_3)_2\cdot\text{COH}$ deprotonates to $(\text{CH}_3)_2\text{CO}^{\cdot-}$. In the presence of N_2O or acetone, e_s^- is converted to $(\text{CH}_3)_2\cdot\text{COH}/(\text{CH}_3)_2\text{CO}^{\cdot-}$ by the reactions in Eqs. 30 and 18, or the reaction of Eq. 20, respectively. The solvated electron in 2-propanol has been utilized to study electron-transfer reactions between aromatic radical anions (donor) and aromatic molecules (acceptor) [16]. The donor–acceptor pairs studied were pyrene–anthracene, pyrene–9,10-dimethylantracene and *m*-terphenyl–*p*-terphenyl. In the first two cases an equilibrium was established and the parameters k_{forward} and k_{back} were measured; this was the first example of the measurement of an equilibrium constant by use of pulse radiolysis. The rate constants for the electron-transfer reactions were examined in terms of the Marcus theory [17].

Pulse radiolysis of 2-propanol has also been used to investigate elementary redox and radical reactions of fullerenes in solution [18]. For example, reduction of C_{60} to $\text{C}_{60}^{\cdot-}$ by e_s^- ($k \geq 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$) and $(\text{CH}_3)_2\cdot\text{COH}$ [$k = (5 \pm 2) \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$] was observed, and $\text{C}_{60}^{\cdot-}$ was found to be stable for hours in the absence of oxygen. C_{60} is insoluble in water, but its reduction in this solvent by $(\text{CH}_3)_2\cdot\text{COH}$ was achieved by imbedding the fullerene in γ -cyclodextrin to form a soluble guest–host complex in a 9:1 (vol %) water:2-propanol mixture. In this case, the reaction rate was two times slower than that in neat 2-propanol. Information was also obtained [18] on the addition of $\cdot\text{CH}_3$ to C_{60} in 2-propanol by the follow-

ing reactions (Eqs. 32 and 33):

3.5.2 Acetone

One-electron oxidants can be generated by pulse radiolysis of acetone containing appropriate solutes. For example, it has been shown that solutions of KSCN and KBr produce $(\text{SCN})_2^{\cdot-}$ and $\text{Br}_2^{\cdot-}$, respectively [19], and, similarly, NO_3^\cdot and $\text{Cl}_2^{\cdot-}$ are formed in solutions of LiNO_3 and LiCl [20]. These oxidants are formed in significant yields, presumably by reaction of the corresponding anion with the solvent radical cation $(\text{CH}_3)_2\text{CO}^{\cdot+}$, and are sufficiently long-lived to permit their electron-transfer reactions to be studied in this solvent.

3.5.3 Acetonitrile

Acetonitrile is a versatile solvent for laboratory use because of its high dielectric constant and aprotic character. Studies of its radiation chemistry show that the radiolysis can be represented by the following steps [21]:

Addition of electron acceptors to acetonitrile confirmed the presence of a transient reducing species through the formation of radical anions of solutes such as biphenyl [21a, 22], pyrene, trans-stilbene, and so forth [21b]. This reducing species has a broad absorption with λ_{max} at 1450 nm, and was shown to exist in the monomeric and dimeric forms (see Eq. 36) from the effect of temperature on the absorbance at λ_{max} [21b]. The monomeric form is responsible for the 1450 nm peak, whilst the dimeric form exhibits a weak maximum at 550 nm superimposed on the tail of the monomeric band. The enthalpy change accompanying the reaction of Eq. 36 has been measured to be $-34.9 \text{ kJ mol}^{-1}$ [21b] so that $\text{CH}_3\text{CN}^{\cdot-}$ is the dominant reducing species at room temperature.

The G value of the reducing species, $G(\text{R})$, has been obtained by measurement of the yields of products of their reaction with various electron acceptors, and values in the range $0.11 \mu\text{mol J}^{-1}$ [21b] to $0.21 \mu\text{mol J}^{-1}$ [23] have been reported. The reason for the variation is likely to be due to assumptions made about the magnitudes of the molar absorption coefficients of the product radical anions. $G(\text{R}) = 0.21 \mu\text{mol J}^{-1}$ was obtained from the yield of $\text{Ru}(332)$ produced by pulse

radiolysis of acetonitrile containing Ru(333), where Ru(333) and Ru(332) represent $[\text{Ru}_3(\mu\text{-O})(\mu\text{-OAc})_6(\text{py})_3]^+$ and $[\text{Ru}_3(\mu\text{-O})(\mu\text{-OAc})_6(\text{py})_3]$, with ruthenium oxidation states of (III, III, III) and (III, III, II), respectively. Since Ru(333) and Ru(332) are stable in acetonitrile, their absorption coefficients are known, and so the reduction yield can be measured accurately. Thus $G(\text{R}) = 0.21 \mu\text{mol J}^{-1}$ is well founded.

In the presence of oxygen, $\text{CH}_3\text{CN}^{\bullet-}$ reacts to form $\text{O}_2^{\bullet-}$ in a reversible process:

with $k_{3,38} = 1.0 \times 10^{11} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ and $k_{-3,38} = 2 \times 10^6 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$, so that $K_{3,38} = 5 \times 10^4$ [23]. Pulse radiolysis of oxygen-saturated solutions of tetracyanobenzene (TCNB) in acetonitrile showed that $\text{O}_2^{\bullet-}$ transfers an electron to TCNB with $k = 6.8 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ [21b].

Acetonitrile is a convenient solvent in which to study, by pulse radiolysis, the one-electron reduction of transition metal complexes that are not stable in water or hydroxylic media. For example, the tantalum compound $[\text{Ta}_2\text{Cl}_6(4\text{-methylpyridine})_4]$ has been shown to be reduced by $\text{CH}_3\text{CN}^{\bullet-}$ with $k = 1.2 \times 10^{11} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ [24]. The absorption spectrum of the product shows the characteristic features of d - d transitions and it was suggested that the added electron is delocalized over the double-bonded Ta=Ta moiety. Another example is the radiolytic reduction of the vanadium(III) complex $[\text{VCl}_3(\gamma\text{-pic})_3]$, where $\gamma\text{-pic}$ is 4-methylpyridine, to the V^{I} derivative via the V^{II} complex [25]. It was shown by pulse radiolysis that the electron adduct of the V^{III} complex decayed in a first-order process with $k = 1.3 \times 10^3 \text{ s}^{-1}$ which is thought to involve loss of Cl^- . The intermediate V^{II} complex had a lifetime of ca. 4 s and decayed by second-order kinetics with $k = 2.5 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ to form $\text{VCl}(\gamma\text{-pic})_3$, which was stable for two or three days.

3.5.4 Chlorinated Hydrocarbons

Early studies of the radiation chemistry of chlorinated hydrocarbons demonstrated the formation of molecular cations of aromatic hydrocarbons with half-lives of the order of a few microseconds [26]. In solutions containing two different aromatic solutes, it was possible to measure the rate of electron transfer from the neutral molecule to the radical cation. Some specific examples of other studies are given below.

Tetrachloromethane

Although various aspects of the radiolysis of CCl_4 are still under debate, this solvent can be used to initiate one-electron oxidation processes. The major oxidant is $^{\bullet}\text{CCl}_3$ formed in Eq. 39:

In the presence of oxygen, the reaction in Eq. 40 generates $^{\bullet}\text{O}_2\text{CCl}_3$, which is also an oxidizing radical. Some examples of the use of pulse radiolysis of CCl_4 solutions to investigate one-electron oxidation are given below.

Compounds that have been shown to be oxidized under these conditions include phenol, *p*-methoxyphenol, TMPD, chlorpromazine [27], and a series of metal-tetraphenylporphyrins (M-TPP) with $\text{M} = \text{Zn}^{\text{II}}, \text{Mg}^{\text{II}}, \text{Cd}^{\text{II}}, \text{Pb}^{\text{II}}, \text{Hg}^{\text{II}}, \text{Pt}^{\text{II}}, \text{Cu}^{\text{II}}, \text{Co}^{\text{II}}, \text{Mn}^{\text{III}},$ and $\text{V}^{\text{IV}}\text{O}$ [28]. The phenols form phenoxyl radicals and the other compounds form radical cations. In the case of M-TPP, the resultant π -radical cations were found to oxidize $\text{Co}^{\text{II}}\text{TPP}$ to $\text{Co}^{\text{III}}\text{TPP}$ with rate constants of $10^5 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ despite the driving force being in excess of 0.4 V. Addition of 1 % pyridine increased the rate constants by at least two orders of magnitude. In each system, the rate constants were fairly insensitive to variations in the driving force, and it was suggested [28] that the rate-determining steps may involve the formation of an intermediate between $\text{Co}^{\text{II}}\text{TPP}$ and $\text{M-TPP}^{\bullet+}$ rather than being a true outer-sphere electron transfer. The enhancing effect of pyridine was thought to be due to its efficiency as an electron-conduction channel rather than its effect on the redox potential.

1,2-Dichloroethane

One-electron oxidation of metalloporphyrins in this solvent is complicated by the production of HCl which rapidly demetallates these complexes. However, addition of pyridine as a base prevents this and allows the oxidation products to be investigated [29]. Under these conditions, the redox processes are similar to those observed in CCl_4 solution (see above).

Dichloromethane

Amongst the radiolysis products of dichloromethane is the highly oxidizing radical cation $\text{CH}_2\text{Cl}_2^{\bullet+}$ [30]. Examples of its use in studies of electron transfer reactions are the oxidation of the fullerenes C_{60} [18], C_{76} , and C_{78} to the corresponding fullerene radical cations $\text{C}_n^{\bullet+}$, and also arenes to $(\text{arene})^{\bullet+}$ [30]. By measurement of the rates of the reaction in Eq. 41 for several different $(\text{arene})^{\bullet+}$, clear evidence was obtained for the Marcus inverted region (see below) from a plot of $\log k$ vs $\Delta G (= \text{IP}_{\text{fullerene}} - \text{IP}_{\text{arene}})$, where IP is the ionisation potential.

3.5.5 2-Methyltetrahydrofuran and 2,2,4-Trimethylpentane

These two solvents were used to investigate the intramolecular electron transfer occurring in a homologous series of eight compounds of general structure A-Sp-B where B is 4-biphenyl, Sp is a rigid saturated hydrocarbon spacer separating A and B, and A is one of the series of eight acceptor groups [31]. Solvated electrons react in a statistical way to give $\text{A}^{\bullet-}\text{-Sp-B}$ and $\text{A-Sp-B}^{\bullet-}$. The rate constant for the electron transfer

Figure 2. Dependence of rate constant on $-\Delta G^\circ$ for electron transfer from $B^{\cdot-}$ to A in $A-Sp-B^{\cdot-}$ generated pulse radiolytically in 2-methyltetrahydrofuran. B = 4-biphenyl, A = 2-naphthyl (1), 9-phenanthryl (2), 1-pyrenyl (3), hexahydronaphthoquinon-2-yl (4), 2-naphthoquinonyl (5), 2-benzoquinonyl (6), 5-chlorobenzoquinon-2-yl (7), 5,6-dichlorobenzoquinon-2-yl (8). (Adapted from Ref. [31]).

could be extracted, and showed a “bell-shaped” dependence on the driving force (see Figure 2). The authors described this as the first unambiguous demonstration of the inverted region predicted by the Marcus theory [17] for highly exoergic reactions [31]. The measurements were based on a 30-ps pulse radiolysis system; nevertheless, some of the intramolecular electron-transfer rates were too fast to be measured, and only their lower limit of $2 \times 10^9 \text{ s}^{-1}$ could be estimated.

3.5.6 Cyclohexane

Pulse radiolysis of solutions of the hexacarbonyl complexes $M(CO)_6$ of the Group-6 metals $M = \text{Cr}, \text{Mo}, \text{and W}$ has been shown to produce the corresponding pentacarbonyls, and the following mechanism was proposed [32]:

The decay of $M(CO)_5$ in the absence of additives, possibly representing addition of

a solvent molecule, and their reactivity towards H_2 , N_2 , and CO were examined [32].

3.5.7 Dimethyl Sulfoxide

Totally reducing and oxidizing conditions can be achieved by the radiolysis of dimethyl sulfoxide (DMSO) containing appropriate solutes [33]. Thus, addition of 1 % acetone or triethylamine provides a good medium for generating only reducing radicals, whilst aerated DMSO containing CCl_4 (or other halogenated hydrocarbons) provides a medium for one-electron oxidation. In each case, the yields of the radicals approach $0.4 \mu\text{mol J}^{-1}$, the sum of the primary yields of e_s^- and $\text{DMSO}^{+\bullet}$ produced by the radiolysis. These properties make DMSO a good solvent for studying one-electron redox processes when they cannot be studied in aqueous solution.

3.5.8 Ammonia

The solvated electron in liquid ammonia was discovered in 1864 by Weyl, and was identified in 1908 by Kraus as an electron, e_{am}^- , in a cavity surrounded by ammonia molecules. It is prepared when an alkali metal, for example sodium, is dissolved in ammonia, to form a stable blue color; under these conditions the electron is present in equilibrium with the metal atom and cation [34]. By contrast, e_{am}^- produced by pulse radiolysis of liquid ammonia is unstable due to its reactions with other radiolysis products; for example, in pure ammonia at -45°C , its lifetime is ca. $7 \mu\text{s}$ [35]. The major decay reactions are thought to involve the oxidizing radicals $\cdot\text{NH}_2$ and $\cdot\text{NH}$ [36], because addition of potassium ethoxide stabilizes e_{am}^- ; this is explicable, since ethoxide ion is expected to scavenge these radicals [36a].

The solvated electron in ammonia has a strong absorption band in the infrared region, and λ_{max} shifts from 1850 nm at 23°C to 1410 nm at -75°C ; this is attributed to the effect of temperature on the orientation of the ammonia molecules in the first solvation shell [37]. On the other hand, $G(e_{\text{am}}^-) = 0.32 \mu\text{mol J}^{-1}$ remains constant over the same temperature range [37]. It is relatively straightforward, therefore, to study one-electron redox reactions in liquid ammonia by pulse radiolysis, but relatively few investigations have been made.

Perkey and Farhataziz [38] have measured the rate constants for the reaction of e_{am}^- with some aromatic hydrocarbons (anthracene, nitrobenzene, phenanthrene, naphthalene, benzamide), with acetone and with dichloromethane, 1,2-dichloroethane, and 1-chloropropane. In the case of the aromatic molecules listed above, the rate constants are an order of magnitude larger than the corresponding values in water, reflecting the lower viscosity of liquid ammonia and indicating that the reactions are diffusion-controlled. In the case of biphenyl (B), the reaction of e_{am}^- was found to be reversible [39]:

with $k_{3.47}/k_{-3.47} = 8.3 \times 10^4$ and $31 \times 10^4 \text{ dm}^3 \text{ mol}^{-1}$ at 21.6 and 10.5 °C, respectively.

Examples of the reduction of metal ions by e_{am}^- include Ag^+ ($k = 1.5 \times 10^{12} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at 23 °C) [40] and Cu^{2+} ($k = 1.5 \times 10^{11} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at –50 °C [36a], and $8.3 \times 10^{11} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at 23 °C [41]). Absorption spectra have been reported for the transient species resulting from the reaction of e_{am}^- with these cations, and also with Ni^{2+} , Hg^{2+} , Cd^{2+} , Pb^{2+} , Zn^{2+} , Tl^{2+} , and Fe^{2+} [41]. There is also evidence that Cu^{2+} is oxidized to Cu^{3+} ($k \approx 6 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at –50 °C) [36a] and Fe^{2+} to Fe^{3+} [41], where the oxidant is thought to be $\cdot\text{NH}_2$.

3.5.9 Solvent Mixtures

These media are essentially an extension of dilute solutions whereby the solute now comprises a significant fraction of the total volume. Nevertheless, the principle remains the same, namely to generate the required radicals. For example, one-electron reduction of the fullerene C_{84} has been effected in nitrogen-saturated toluene/2-propanol/acetone (8:1:1) [42]. Here the solvent primary radicals are converted to $(\text{CH}_3)_2\cdot\text{COH}$ by reduction of acetone and oxidation of 2-propanol.

Another example is the use of solvent mixtures to study protonation reactions. Thus, pulse radiolysis of acetone/2-propanol/carbon tetrachloride has been shown to produce HCl within approximately 100 ns, and this system has been used to measure rates of fast protonation reactions [43].

It is clear from the foregoing descriptions that pulse radiolysis provides a very versatile way of generating one-electron redox reagents under a wide range of solvent conditions that can be finely tuned to accommodate the reactions of interest.

3.6 Pulse Radiolysis

3.6.1 Historical Perspective

It was in 1960, ten years after the publication of the first detailed description of flash photolysis by Porter [44], that the analogous technique of pulse radiolysis was introduced in four separate laboratories: by McCarthy and MacLachlan at Du Pont Experimental Station, Wilmington, Delaware [45], by Matheson and Dorfman at Argonne National Laboratory, Illinois [46], by Keene et al. at AEI Ltd., Manchester [47], and by Steele and Boag at Mount Vernon Hospital, Northwood [48]. Actually, as noted by Boag [49], the idea of mimicking flash photolysis by using single pulses of high energy electrons from a linear accelerator was already being developed in 1953. The lapse in time between the advent of flash photolysis and the first experiments in pulse radiolysis was due mainly to the fact that electron accelerators able

to produce single short pulses of radiation of sufficient intensity were still under development when flash photolysis became operative. In addition to this, these machines were large, expensive, and for safety reasons, required housing in buildings designed to protect personnel from the radiation [50].

The first paper describing pulse radiolysis results was that of McCarthy and MacLachlan [45]. They gave a detailed description of the apparatus and technique, and reported on the identification of the spectrum of the benzyl radical generated from benzyl chloride dissolved in cyclohexane, ethanol, ethanol with glycerol, and glycerol. The data were in good agreement with those obtained from flash photolysis studies made by Porter and Windsor in 1957 [51]. Matheson and Dorfman [46] also identified the benzyl radical in cyclohexane and examined other systems in which transient absorption spectra were observed and tentatively attributed to the allyl radical and the inorganic radicals $I_2^{\cdot-}$, BrO^{\cdot} , BrO_3^{\cdot} . The first experiments at Mount Vernon Hospital [48] and Manchester [47] were focused mainly on the oxidation of ferrous ion to ferric ion in aqueous sulfuric acid solution, the basic process of the Fricke dosimeter [52].

Following these first reports, pulse radiolysis studies were soon directed towards the identification of transient species and the characterization of their reaction kinetics in a variety of solvents [53]. Examples of such work are: a) Determination of the rate constants for the addition of the hydroxyl radical to benzene in aqueous solution to form the hydroxycyclohexadienyl radical and its subsequent reaction with oxygen to form the corresponding peroxy radical [54]; and b) The characterization of the transient species produced in ethanol and aqueous solutions of ethanol [55]. In the next few years, the number of laboratories with pulse radiolysis facilities grew rapidly and there was a burgeoning interest in identifying and characterizing the transient species generated by ionizing radiation. Some of the landmark discoveries in those early years are described briefly in the following paragraphs.

Absorption spectrum of the hydrated electron

The discovery in 1962 of the intense absorption band of e_{aq}^- (λ_{max} 720 nm, ϵ_{max} 1900 m² mol⁻¹) [56] in pulse radiolysis experiments on aqueous solutions was made almost simultaneously at Mount Vernon Hospital [57] and Manchester [58], and provided an extremely useful method for measuring the rate constants for the reaction of this species with a variety of compounds. As mentioned in the Introduction, reactions of the hydrated electron are electron-transfer reactions. The first paper dealing with this type of measurement appeared in 1963 [59] and contained the rate constants for the reactions of e_{aq}^- with H^+ , H_2O_2 , and O_2 . Many other rate constants for the reactions of e_{aq}^- were determined in the following years. The NDRL/NIST Solution Kinetics Database, Version 3, which covers the literature up to 1994, contains nearly two thousand entries for this type of reaction, almost all of them obtained by means of pulse radiolysis [7a]. In many cases, the rate constant for a given reaction has been determined more than once; for example, the rate constants for the reaction of e_{aq}^- with H^+ , NO_3^- , $C_6H_5NO_2$, Ag^+ , Cu^{2+} , and MV^{2+} (1,1'-dimethyl-4,4'-bipyridinium) have been determined 19, 16, 14, 11, 10, and 8 times, respectively [7a].

The hydrogen atom and hydroxyl radical

Because the H \cdot atom and the \cdot OH radical possess only small absorptions in the UV region [56], the first rate constants for their reactions with a variety of substrates were obtained by following the formation of an absorbing product or by using the competition kinetic method [60]. A prime example of the use of this method is the study of the rate of oxidation of hexacyanoferrate(II) by \cdot OH as a function of the pH of the aqueous solution [61]. By following the formation of hexacyanoferrate(III) at 420 nm, Rabani and Matheson [61] measured the value of $k_{3.48}$ and found it to decrease sharply with increasing pH at pH > 12.

The data were interpreted (correctly) in terms of the dissociation of \cdot OH to $\text{O}^{\cdot-}$ with $\text{p}K_a(\cdot\text{OH}) = 11.9 \pm 0.2$ on the basis that $\text{O}^{\cdot-}$ is unreactive towards $\text{Fe}(\text{CN})_6^{4-}$.

In 1965, Adams et al. [62] obtained the absolute rate constants for the reaction of \cdot OH with a number of solutes, using the competition method; the reactions of \cdot OH with CO_3^{2-} , SCN^- , and SeO_3^{2-} that give the absorbing radicals $\text{CO}_3^{\cdot-}$, $(\text{SCN})_2^{\cdot-}$ and $\text{SeO}_3^{\cdot-}$, respectively, were used as references. Similarly, Thomas [63] determined the rate constant for the reaction of \cdot OH with I^- by following the formation of $\text{I}_2^{\cdot-}$ (λ_{max} 385 nm, ϵ_{max} 940 m 2 mol $^{-1}$) [56], and from that derived the rate constants for other reactions of the \cdot OH radical [63]. The NDRL/NIST Database cited above contains 1787, 715, and 171 entries for the reactions of \cdot OH, H \cdot , and $\text{O}^{\cdot-}$, respectively [7a].

In 1965, the first International Symposium on Pulse Radiolysis was held in Manchester and the scientific contributions and discussions were published in book form. One of these contributions [64] described what is probably the first determination, by means of pulse radiolysis, of rate constants for electron transfer from transient species, obtained from the reaction of e_{aq}^- with various metal ions, and MnO_4^- ; these reactions were followed by monitoring of the disappearance of the absorbance of MnO_4^- [64]:

where $\text{M}^{n+} = \text{Cr}^{3+}$, Ni^{2+} , Co^{2+} , Cd^{2+} , Cu^{2+} , Ag^+ .

Pulse radiolysis was also applied very early to the estimation of the redox potentials of transient species. By examination of the reactivity of the transient species Zn^+ , Cd^+ , and Pb^+ towards Cd^{2+} and Pb^{2+} , Zn^{2+} and Pb^{2+} , and Zn^{2+} and Cd^{2+} , respectively, Baxendale et al. [65], were able to show that $E^\circ(\text{Zn}^{2+/+}) < E^\circ(\text{Cd}^{2+/+}) < E^\circ(\text{Pb}^{2+/+})$ which is in agreement with subsequent evaluations [66a]. Since then, many redox potentials of transient species have been determined by means of pulse radiolysis and have enriched the specialized compilations [66].

In 1967, the first three-stage electron-transfer process examined by pulse radiolysis was reported [67]. Such a cascade process is of relevance to electron transport in biological systems. By irradiating an aqueous solution containing acetone (0.82 mol dm^{-3}), acetophenone ($3.34 \text{ mmol dm}^{-3}$), and benzophenone ($72 \text{ } \mu\text{mol dm}^{-3}$) at pH 13, Adams et al. [67] were able to observe, at $2 \text{ } \mu\text{s}$ after the pulse, the spectrum of the acetophenone radical anion ($\lambda_{\text{max}} 445 \text{ nm}$, $\epsilon_{\text{max}} 260 \text{ m}^2 \text{ mol}^{-1}$) [68] originating from the reduction of acetophenone by the $(\text{CH}_3)_2\text{CO}^{\bullet-}$ radical. In the following $50 \text{ } \mu\text{s}$, the acetophenone radical anion reacted with benzophenone ($k = 7.8 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$) so that the absorption band at 445 nm disappeared and that of the benzophenone radical anion ($\lambda_{\text{max}} 600 \text{ nm}$, $\epsilon_{\text{max}} 480 \text{ m}^2 \text{ mol}^{-1}$) [68] was formed.

One-electron redox equilibria

The examples of redox reactions described above were measured under conditions where they went to completion in the forward direction. However, when the reduction potentials of the electron donor (D) and acceptor (A) are not very different, equilibrium conditions can be achieved where all the species in Eq. 52 are present:

The first determination of an equilibrium constant by measurement of the concentrations of the transients at equilibrium involved the system duroquinone (DQ) and oxygen [69]:

where $K_{3.53} = 2.3 \times 10^{-2}$ was obtained.

The kinetic method provides another way of obtaining equilibrium constants by the measurement of the rate of approach to equilibrium. It relies on the back reaction having a measurable effect on the forward electron-transfer reaction in a scheme comprising Eqs. 52 and 54:

where the rate equation is Eq. 55 and the integrated form is Eq. 56:

$$-d[\text{D}^-]/dt = k_{3.52}[\text{D}^-][\text{A}] - k_{-3.52}[\text{A}^-][\text{D}] + k_{3.54}[\text{X}] \quad (55)$$

$$\ln[\text{D}^-]_t - [\text{D}^-]_e = C_1 - (k_{3.52}[\text{A}] + k_{-3.52}[\text{D}])t \quad (56)$$

Here $[\text{A}^-]_e$ is the concentration of $[\text{A}^-]$ at equilibrium and C_1 is a constant. Values of $(k_{3.52}[\text{A}] + k_{-3.52}[\text{D}])$ can be obtained from a plot of $\ln[\text{A}^-]_t - [\text{A}^-]_e$ versus t and then $k_{3.52}$, $k_{-3.52}$, and hence $K_{3.52}$, can be calculated from a plot of $(k_{3.52}[\text{A}] + k_{-3.52}[\text{D}])$ vs. $[\text{A}]$ at constant $[\text{D}]$. As mentioned in Section 3.5.1, the first

report of such a measurement was by Arai and Dorfman [16] for electron transfer from the pyrenide anion to anthracene and 9,10-dimethyl anthracene in 2-propanol.

Another example of the determination of a redox equilibrium by pulse radiolysis is the measurement of the reduction potential of silver aggregates, Ag_n , as a function of the aggregation number n . Such measurements are of intrinsic value in understanding photographic development processes [70].

The principle of the method is to produce, in the same pulse, silver atoms and an electron donor, in this case the sulfonatopropylviologen radical anion ($\text{SPV}^{\bullet-}$) for which $E^\circ(\text{SPV}/\text{SPV}^{\bullet-}) = 0.41 \text{ V}$; the aggregation of silver atoms and the decay of $\text{SPV}^{\bullet-}$ are then followed by time-resolved optical spectroscopy. After a certain time, during which $[\text{SPV}^{\bullet-}]$ remains constant, the decay of this radical and the growth of Ag_n become correlated, showing that Ag_n has reached a critical size where it is able to accept an electron from $\text{SPV}^{\bullet-}$. The proposed mechanism [70] involves autocatalytic growth of Ag_n through the following reaction sequence:

The data obtained [70] show that the reaction in Eq. 58 commences when $n = 4$ so that $E^\circ(\text{Ag}_5^+/\text{Ag}_5) \approx 0.41 \text{ V}$.

Pulse radiolysis at high pressure

Of particular interest in the radiation chemistry of water is the equilibrium (Eq. 59) between e_{aq}^- and H^\bullet since one can obtain from it the reduction potential of e_{aq}^- :

To measure the back reaction, it is necessary to generate H^\bullet in alkaline solution, and this was achieved by Matheson and Rabani [71] who developed a pulse radiolysis cell capable of operating at a pressure of 100 bar. In this way they were able to produce H^\bullet effectively during the pulse ($0.4 \mu\text{s}$) by the following reaction (Eq. 60):

Subsequently, Hentz et al. [72] were able to carry out pulse radiolysis studies at pressures up to 6.3 kbar. Some of the principal results obtained for aqueous solutions were: a) The absorption spectrum of e_{aq}^- showed only a small blue shift ($d\lambda_{\text{max}}/dP$) of 0.06 eV/kbar up to 4.88 kbar and thereafter no further change; this indicates that the cavity volume of e_{aq}^- is very small ($V = 7 \text{ ml mol}^{-1}$); and b) The diffusion coefficient of e_{aq}^- changes negligibly with pressure, in contrast to normal ions and molecules.

In liquid ammonia at 23°C , however, ($d\lambda_{\text{max}}/dP$) at low pressure is about four times greater than it is in water, consistent with the much larger cavity of e_{am}^- ($V = 98 \text{ mL mol}^{-1}$) being more compressible [73].

Pulse radiolysis at high temperature

Pulse radiolysis studies of liquids at high temperature must necessarily be carried out at pressures sufficiently high to prevent boiling. The first pulse radiolysis experiments at high temperature were conducted by Michael et al. [74] who determined the spectrum of e_{aq}^- in the temperature range -4 to 390°C which the use of small suprasil capillaries above 200°C .

It was some ten years before any systematic program of pulse radiolysis at high temperature had begun when Christensen and Sehested [75] had available a pulse radiolysis cell that enabled measurements to be made up to 320°C and 140 bar. This work focused on the radiation chemistry of water at elevated temperatures because of its relevance to the radiation chemistry occurring in the primary cooling circuits of pressurized water reactors used for electricity generation.

The study at elevated temperatures of reactions that are diffusion-controlled at ambient temperature, can be particularly informative, since the kinetics of a diffusion-controlled reaction reveals little information about the chemical mechanism. The general expression for a time-independent rate constant in solution is [76]:

$$1/k_{\text{obs}} = 1/k_{\text{diff}} + 1/k_{\text{react}} \quad (61)$$

where k_{obs} , k_{diff} , and k_{react} are the observed, diffusion-controlled, and activation-controlled rate constants, respectively. Thus, by raising the temperature sufficiently, it has proved possible to make the diffusion process so fast that it is no longer rate-limiting and information specific to the chemical, or activated step is revealed [77]. Such studies have shown that the reactions of: 1) e_{aq}^- with N_2O , NO_3^- , NO_2^- , SeO_4^{2-} , $\text{S}_2\text{O}_3^{2-}$, and phenol [78], and 2) $\cdot\text{OH}$ with benzene and a number of substituted benzenes [79], are all reversible. The experimental manifestation of this behavior is that Arrhenius plots for k_{obs} are nonlinear. Similarly, nonlinear Arrhenius behavior is exhibited by k_{obs} for radical-radical combination reactions because there is no energy barrier to the chemical step so that $1/k_{\text{react}}$ becomes the dominant term on the right-hand side of Eq. 61 as the temperature is raised.

General chemistry

The contribution of pulse radiolysis to general chemistry is very significant, and this is exemplified by the following studies of transition metal complexes. The reduction of tris(2,2'-bipyridine)ruthenium(III) ion by the hydrated electron was the first example of this type of reaction to show clearly the formation of a product in an electronically excited state [80]:

The spectrum of the chemiluminescence produced by this reaction corresponded closely to the emission spectrum obtained on photoexcitation of $\text{Ru}(\text{bpy})_3^{2+}$ [80].

In their reactions with transition metal complexes, free radicals may attack directly at the metal center or at a ligand to produce a coordinated free radical, which may then undergo electron transfer involving the metal center. The first observation

of a coordinated free radical was reported by Hoffman and Simic who found that the reaction of $\cdot\text{OH}$ with benzoatopentamminecobalt(III) generated a product with an absorption spectrum that was very similar to that obtained by reaction of $\cdot\text{OH}$ with benzoate/benzoic acid [81]:

The absorption spectrum of the coordinated radical was intermediate between those of $\cdot\text{C}_6\text{H}_5(\text{OH})\text{CO}_2\text{H}$ and $\cdot\text{C}_6\text{H}_5(\text{OH})\text{CO}_2^-$, in keeping with the effect of the carboxylate group being coordinated to the metal center [81]. There was no evidence in this example for electron transfer from the ligand radical to the cobalt(III) center. On the other hand, reaction of e_{aq}^- with the same complex generated Co^{II} within the time resolution ($<1 \mu\text{s}$) of the measurements. By contrast, reaction of e_{aq}^- , $\text{CO}_2^{\cdot-}$ or $(\text{CH}_3)_2\cdot\text{COH}$ with *p*-nitrobenzoatopentamminecobalt(III) resulted in the added electron being localized on the *p*-nitrobenzoato ligand [82]. This species then decayed by a first-order process ($k = 2.6 \times 10^3 \text{ s}^{-1}$), representing intramolecular electron transfer from the coordinated radical to the metal center. This was the first reported observation using pulse radiolysis of this type of process [82].

Detection methods

Optical detection in early pulse radiolysis experiments was based mainly on the spectrophotographic recording method but this was abandoned in the mid-sixties in favor of the photoelectric method. The traces on the oscilloscope screen were photographed, usually enlarged and reproduced on graph paper before being subjected to analysis. A common feature of pulse radiolysis assemblies now is the use of fast-transient digitizing recorders coupled to computers, which allow the rapid collection and manipulation of the data. Devices such as optical multichannel analyzers (OMA) [83] and streak cameras [84] can be used to get complete spectra after a single pulse. A method for the simultaneous recording of optical changes on multiple time scales has recently been described [85].

Other methods of monitoring the reactions and products were soon introduced. These included electrical conductivity in 1962 [49], magnetic resonance (EPR in 1968 [86] and NMR in 1976 [87]), polarography in 1971 [88], light scattering (Rayleigh scattering in 1974 [89] and Raman scattering in 1976 [90]), and microwave absorption in 1973 [91]. Of these methods, conductivity is the most widely used after optical measurements, and the others are all limited to specialist laboratories.

3.7 Pulse Radiolysis Facilities

In the first monograph dedicated to pulse radiolysis, published in 1969 by Matheson and Dorfman [92], which still represents a most valuable source of information on the various aspects of the technique, it is reported that by the end of 1968 at least 27

Figure 3. Schematic of a pulse radiolysis facility with optical and conductometric detection. C: cell; CS: conductivity signal; D: dose monitor; DI: door and interlock system; F: filters; L: lens; MC: monochromator; M_1 : mirrors; PD: photodetector; S: shutter.

laboratories were equipped with pulse radiolysis facilities. These laboratories were located in the US (11), UK (6), and Canada (4); Denmark, France, Germany, Israel, Switzerland, and the USSR possessed one pulse-radiolysis laboratory each. In the following years, many other institutions in Europe, Japan, and other parts of the world installed pulse radiolysis facilities. At the same time, some of the laboratories that pioneered pulse radiolysis made great improvements to their facilities and introduced other methods of detection.

3.7.1 A Typical Modern Pulse Radiolysis Facility

A typical pulse radiolysis facility with optical and conductometric detection is represented schematically in Figure 3. The essential parts of the system are: accelerator and related controls, sample cell, light source with its power supply and pulser unit, light shutter, filters, lenses, and mirrors to bring the analyzing light beam from the light source through the sample cell to the monochromator(s) and the photodetector, transient recorder (oscilloscope or transient digitizer), and computer. The computer used to control the experiment and to collect the data can be connected to a printer and/or a plotter and to other computers for storage and analysis of the data. Various components of the assembly such as the lamp pulser, shutter, filters,

lenses, dose monitor, and monochromator(s) can be computer-controlled. In Figure 3, for the sake of clarity, the connections between the computer and these components have been omitted. For the same reason, the possibility of monitoring the temperature of the sample has not been indicated. The figure shows the presence of a shielding wall of appropriate thickness that separates the accelerator room from the control room; the door connecting the two rooms is controlled by an interlock system, the complexity of which generally increases with increasing energy of the electron beam. In some laboratories, the control room is fitted with a Faraday cage surrounding the data-collection station [93]. In other cases, the Faraday cage is placed around the accelerator so that the electrical interference is contained at source [94]. In Figure 3 only one exit port of the electron beam has been indicated, which is the most common situation. In some laboratories, however, by means of bending magnets it is possible to bring the electron beam to different exit ports equipped for different types of experiments [95, 96]. In other cases, the instrumentation needed for experiments of different nature is mounted on interchangeable benches. This solution has been adopted, for example, at the FRAE Institute in Bologna, where the bench supporting the cell holder and the components of the optical detection system that reside in the accelerator room can rapidly replace the bench supporting the apparatus used for radiation processing [97]. Finally, closed-circuit television can provide useful remote visual monitoring and control of some aspects of the experiment.

A brief description of the major components of a pulse radiolysis system will be given in the following; whenever possible, references will be given to the original papers where the specific solutions adopted in the various laboratories are described in detail.

Accelerators

Almost all the work in pulse radiolysis is based on the use of three types of electron accelerators: linear accelerators (linacs), Van de Graaff accelerators, and Febetrans. The first accelerator used by Keene at Manchester was a 4-MeV linac with pulses of 0.2–2 μ s duration [47a]; this was replaced in 1967 with an 8–12-MeV linac capable of delivering pulses from 5 ns to 5 μ s duration [93]. Further improvements made to the Manchester system up to 1989 have been documented [93]. Similarly, the 13-MeV linac used at Argonne in 1960 by Matheson and Dorfman produced pulses of 0.4 to 5 μ s duration [46], whereas in 1989 the equipment comprised a 20-MeV linac, capable of producing pulses from 25 ps to 10 μ s duration, and a 3-MeV Van de Graaff accelerator, which is dedicated to EPR and magnetic resonance studies (see below) [95, 98].

The parameters that make a given accelerator more or less suitable for a specific pulse radiolysis experiment are the pulse length, the energy, the size of the beam, the dose per pulse, and the repetition rate. In general, the shorter the pulse, the better it is, since the length of the pulse usually determines the resolution time of the system. However, the cost of an accelerator increases significantly with decreasing pulse length. Many pulse radiolysis systems are based on machines that deliver pulses of some nanoseconds up to microseconds duration and this is quite adequate for many

Figure 4. Dependence of dose deposition on depth in water. (Adapted from J.W. Boag in *Action Chimiques et Biologiques des Radiations*, Vol 6 (Ed.: M. Haissinsky), Masson et Cie., Paris, 1963, p. 5).

chemical applications. Some detailed information on accelerators can be found in a number of publications [92, 99–101].

The first nanosecond facility in China was installed in 1990 at the Shanghai Institute of Nuclear Research [102]. Other new accelerators for radiolysis experiments have been recently installed at the Institute of Nuclear Chemistry and Technology, Warsaw [96], at the Radiation Laboratory of the University of Notre Dame [103], and at the Chemistry Department of the Brookhaven National Laboratory [104].

Pulse radiolysis with picosecond time resolution has been developed, or is planned, in only a few laboratories. These rather special facilities are described separately in Section 3.9.

The energy of the electron has influence on the penetration of the beam, as shown in Figure 4. If the energy is very low, for example, 600 keV as it is with a Febetron 706, special care must be taken in the construction of the irradiation cell (see below). Energies higher than 20 MeV are unnecessary and may represent a problem because of induced radioactivity and additional costs for shielding. With only a few exceptions (Orsay 0.6 MeV, Osaka 28 MeV, Ottawa 35 MeV, Sapporo 45 MeV, and Amsterdam 85 MeV), the majority of the pulse radiolysis laboratories have accelerators that generate electron beams of ca. 2 to 20 MeV energy. Of the accelerators presently in operation, approximately 50 % are linacs (2–20 MeV), 25 % are Van de Graaffs (2–5 MeV) and 25 % are Febetrans (mostly Febetron 705, 2 MeV). In general terms, a beam energy of about 10 MeV gives ample flexibility as far as the assembling of a variety of experiments is concerned.

The size of the beam should match that of the cell, particularly when quantitative information is to be gained from absorbance measurements. It can be modified to some extent by means of scatter plates interposed between the exit window and the cell (if the energy of the electron beam allows this to be done) or by means of focusing magnets. In general, the beam is kept small and as uniform as possible and the optical path length is increased by use of multiple reflection cells (see below). For conductivity experiments (see below), the size of the beam should match the volume between the electrodes.

The dose per pulse that is used in pulse radiolysis experiments, for example, with aqueous solutions, can vary between a few tenths of a Gy and several hundred Gy, depending on the nature of the experiment ($1 \text{ Gy} = 1 \text{ J kg}^{-1}$ and a dose of 1 Gy generates ca. $0.6 \mu\text{mol dm}^{-3}$ of radicals in water). In general, because of the greater sensitivity of the detection method, conductivity experiments (see below) require lower doses than those needed in optical measurements. A low dose per pulse is required when radical-radical reactions are to be minimized or when pseudo-first-order conditions are to be maintained, for example, when dealing with highly absorbing substrates so that they can be used only at low concentration. Under these circumstances, which could be associated with intrinsically weak signals, averaging procedures to increase the signal-to-noise ratio may become necessary. These procedures are somewhat impractical with Febetrons since the pulse repetition rate of these accelerators is low, approximately one pulse every 1–2 minutes; with linacs and Van de Graaffs, the pulse repetition rate is not a limitation for data averaging. It is important, however, to maintain a constant dose per pulse during averaging, particularly if the study involves measuring second-order reaction kinetics.

Some experiments may require the use of different doses. Depending on the accelerator, this can be done by a change of the length of the pulse (if the experiment allows it), the focusing of the beam and/or the beam current. Alternatively, the amount of radiation that reaches the sample cell can be varied by means of scatter plates of variable thickness or, particularly with Febetrons, metal shields with holes of different sizes [105].

Sample cell and flow system with optical detection

The majority of the pulse radiolysis work deals with the monitoring of changes in absorbance and/or conductivity (see below) induced by the irradiation of solutions (in particular aqueous solutions). Many types of cells used for the measurement of transient optical absorption have been described in the literature, their shapes and sizes depending on a variety of factors such as energy and size of the electron beam, nature of the experiment to be performed, scarcity and/or cost of substrate to be examined, and so forth. The material from which the cells for optical measurements are made can vary, but the optical windows are generally made of Spectrosil quartz which does not darken when irradiated. When the energy of the electron beam is of the order of 10 MeV , there are no particular restrictions as far as the design of the irradiation cell is concerned. With electron beams of this type, rectangular or cylindrical cells with 1–3 mm-thick walls, optical path lengths of 0.5 to 5–10 cm and cross sections of less than 0.1 cm^2 up to $1\text{--}2 \text{ cm}^2$ are commonly used. A short path

length is obviously needed when the sample to be irradiated presents an intrinsically high absorbance in the spectral region to be examined or when dealing with fast (picoseconds) measurements (see Section 3.9). With non-absorbing samples, the tendency is to increase the optical path length as much as possible, to be compatible with the size of the electron beam and the sample availability. Multiple reflection cells can also be used to increase the optical path length and to keep the volume of the sample to be irradiated relatively small. A multiple reflection cell that "enabled the use of long optical paths of up to 80 cm with an actual cell length of only 4 cm" has been described [106]. When the energy of the electron beam is low, the thickness of the wall through which the electron beam enters the sample and that of the sample itself must be reduced accordingly. For example, a cell with a 0.2-mm-thick electron wall, 1-cm optical path length and a cross section of 0.05 cm² is used for pulse radiolysis experiments with 600 keV electrons from a Febetron 706 [107].

Pulse radiolysis experiments with optical and/or conductometric detection often require the solution to be changed after each irradiation pulse. As a consequence, systems have been devised to perform this operation which, in many cases, is remotely controlled. The solution to be examined, sparged with an inert gas (to remove O₂) or saturated with a specific gas, for example, nitrous oxide, is contained in a flask or a syringe (see Figure 5) which is connected to the irradiation cell. The solution is made to flow into the cell by maintenance of a small excess gas pressure in the flask or by mechanical operation of the plunger of the syringe. A motor-driven tap or an electromagnetic valve between the reservoir and the cell (or after the cell) will stop the solution flow at any required time. The cell can be drained before being refilled with fresh solution or, more simply, the irradiated solution is pushed away by fresh solution. When the experiment requires many samples of the same solution because of averaging procedures and/or multiwavelength examinations, the change of the solution can also be under computer control; in some cases, particularly when the solution is available in large amount, it is left flowing at the appropriate rate during the entire experiment. In all cases it is desirable that the solution in the cell is completely refreshed between pulses to prevent any interference from accumulated reaction products.

Figure 6. Schematic representation of a rapid-mixing device for pulse radiolysis. C: cell; CS: calibrated syringes (2 mL); D: drain; EB: electron beam; FP: firing piston; GI: gas inlet; RS: reservoir syringes; 3WT: 3-way tap.

In Figure 3, the electron beam and the monitoring light beam are perpendicular to each other. An alternative solution, that of the analyzing light beam being col-linear with the electron beam, has also been adopted [45, 108].

In some cases, because of decomposition phenomena, it may be necessary to prepare the solution to be irradiated “immediately” before the pulse. A procedure of this type, based on the use of a rapid-mixing device placed before the irradiation cell, has recently enabled Czapski et al. to investigate by pulse radiolysis the species HCO_3^- and H_2CO_3 in solutions that were made acidic approximately 50 ms before the pulse so that their decomposition was kept at a low level. From this study it has emerged that the HCO_3^\cdot radical is a strong acid ($\text{p}K_a < 0$) [109]. An example of a rapid mixing device for pulse radiolysis studies is shown in Figure 6.

A setup for pulse radiolysis of aggressive substances, such as anhydrous HNO_3 , has been described [110]. The all-glass flow system is designed to operate by remote control and each point where the unit has contact with the surrounding atmosphere is protected by a suitable guard tube.

Most pulse radiolysis experiments are performed with solutions at ambient temperature. In other cases, the temperature of the sample is kept constant or it is varied by means of suitable thermostatic systems. The construction details of a variable-temperature (from ca. -160 to $+150^\circ\text{C}$) cell housing adaptable to a pulse radiolysis flow system have been given [111]. An alternative method of carrying out pulse radiolysis studies on liquids at high temperature (up to 300°C) is to enclose the whole assembly of cell, reservoir syringe, and flow system in a pressure vessel [112]. Only the cell is located within a heating block and the reservoir remains at ambient temperature. With this method, the sample in the cell can be changed remotely as in conventional experiments.

A high-pressure cell, originally utilized in flash-photolysis experiments where limitations caused by low beam penetration do not exist, has been adapted for measurements up to 200 MPa in pulse radiolysis experiments to be performed at ambient temperature with a beam energy as low as 2 MeV [113].

Sometimes it can be informative to compare the permanent spectral changes induced by the pulse irradiation of a solution with those detected at the end of the longest time that is permitted by the pulse radiolysis detection system. This can be done by use of a spectrophotometric cell attached to a bulb provided with a stop-cock that allows the sample to be adequately prepared, for example, with the aid of a vacuum line. The cell is then placed in front of the accelerator and is used as a normal pulse radiolysis irradiation cell. When the pulse radiolysis experiment is complete, the cell can be transferred into a spectrophotometer, preferably a diode-array type, where spectra and/or kinetic data can be obtained. Samples irradiated in this way can also be used to examine the reactivity of the permanent products originating from the irradiation toward a specific reagent, for example O_2 . Examples of "slow" pulse radiolysis experiments of this type have been reported in the literature [114]. A "single-shot" pulse radiolysis setup, where a diode-array spectrophotometer is connected to the normal optical system by means of a fiber-optic light guide, has been used for studies over times greater than about ten seconds [93].

Another system, based on the familiar stopped-flow method, has been developed specifically to measure relatively slow reactions of the superoxide radical with molecules of biological interest [115]. One of the reactants, $O_2^{\cdot-}$, is generated by radiolysis of oxygenated formate solution in one arm of the stopped-flow apparatus before this solution is mixed with the second solution containing the solute of interest and passed into a spectrophotometer. For solutes that have suitable absorption spectra, rate constants can be determined under pseudo-first-order conditions by the fading of the solute absorbance being monitored. Rate constants of the order of 10^4 – 10^5 dm^3 mol^{-1} s^{-1} are readily measured in this way. In the case where the solute is transparent, the reaction rate can be obtained from the rate of disappearance of $O_2^{\cdot-}$ which absorbs strongly at 250 nm [56]. However, in this case it is not possible to judge whether the superoxide radical undergoes oxidation or reduction, or whether its rate of decay is the termination step of a fast chain reaction.

This difficulty can be overcome by measurement of the depletion of O_2 in the reaction with use of an oxygen electrode [115], and then four situations can be distinguished. Firstly, there may be no reaction between $O_2^{\cdot-}$ and the solute S, so that $G(-O_2) = 0.5G(O_2^{\cdot-})$ because of the stoichiometry of the reaction given by Eq. 64.

Secondly, when $O_2^{\cdot-}$ is oxidized, $G(-O_2) = 0$; thirdly, when $O_2^{\cdot-}$ is reduced, $G(-O_2) = G(O_2^{\cdot-})$; and lastly, when a chain reaction occurs by the propagating steps represented by Eqs. 65 and 66, $G(-O_2) \gg G(O_2^{\cdot-})$.

A combination of optical kinetic measurements and oxygen electrode measurements serves to evaluate rate constants and indicate the direction of electron transfer, as well as confirming the overall stoichiometry of the reaction.

Dose monitor and dosimetry

Inasmuch as the irradiation dose can change from pulse to pulse, it is desirable and often necessary to monitor the dose delivered by each pulse. This can be done by means of various devices: a toroidal coil placed around the electron beam [116], a secondary emission chamber placed just before the exit window of the accelerator [13], a charge collector placed in the proximity of the irradiation cell [117], or, electron beam energy permitting, behind the irradiation cell [118]. With these devices, a parameter is obtained representing the relative dose of each pulse; calibration against chemical dosimeters provides the knowledge of the absolute irradiation dose associated with each individual pulse.

The chemical dosimeter that is used most frequently is the thiocyanate dosimeter [119]. Other chemical dosimeters for pulse radiolysis are ferrocyanide [119], modified Fricke (Super-Fricke) [119], hydrated electron [120], O₂-saturated solutions of potassium iodide [112], and N₂O-saturated solutions of methylviologen and formate [118]. The C(NO₂)₄ (tetranitromethane, TNM) dosimeter is used in pulse radiolysis experiments with simultaneous optical and conductometric detection [121–124]. The composition and characteristics of the various chemical dosimeters used for pulse radiolysis with optical detection are listed in Table 8.

As far as possible, dosimetry should be carried out under the same conditions used for the experiments, to avoid errors due to the possible nonlinear response of the dose monitor. The choice of dosimeter depends on the following factors:

- 1) Its sensitivity, that is, the value of $G\epsilon$ (m² J⁻¹), where G (μmol J⁻¹) is the yield of product and ϵ (m² mol⁻¹) is the molar absorption coefficient at the monitoring wavelength;
- 2) The formation time of the product;
- 3) The stability of the product.

For low dose per pulse, a large value of $G\epsilon$ is desirable; when the response time of the optical detection system is slow, the product should be relatively stable.

The thiocyanate dosimeter is not suitable when the dose per pulse is large and/or the detector response time is long, because the product (SCN)₂^{•-} decays in a fast self-reaction, the rate of which increases with increasing dose. For these conditions it is better to use the ferrocyanide dosimeter for high dose and the methylviologen dosimeter for low dose, because the respective products Fe(CN)₆³⁻ and MV^{•+} are stable. The hydrated electron dosimeter is suitable for low doses; it should be used cautiously, since the G value changes with measurement time.

In pulse radiolysis experiments with optical detection, the measured quantity is optical absorbance, so any measured absorbance A can be quantified as a value of $G\epsilon$ with Eq. 67:

$$\frac{(A/V_{DM})}{(A/V_{DM})_{\text{dosimeter}}} = \frac{(G\epsilon)}{(G\epsilon)_{\text{dosimeter}}} \times \frac{\rho_{\text{dosimeter}}}{\rho} \quad (67)$$

where V_{DM} represents the reading of the dose monitor. Because the absorbed dose

depends on the electron density ρ (electrons g^{-1}), corrections should be made for any difference in this quantity between the test solution and the dosimeter by inclusion of the second factor on the right-hand side of Eq. 67. Since absorbance is proportional to the optical path length, it is obvious why dosimetry should be carried out in the cell used for the experiment.

Analyzing light, optical system and monitoring devices

High-pressure xenon arc lamps of various power, from 50 to 1000 W, but mostly 450 W, are the standard light sources for pulse radiolysis with optical detection. The spectrum of this type of lamp satisfactorily covers the region that is usually explored in pulse radiolysis experiments based on the use of photomultipliers and photodiodes as optical detectors. Lamps of this type with quartz or sapphire windows to extend their spectrum in the UV and NIR regions, respectively, are commercially available. Xenon lamps can be pulsed, usually for a few milliseconds, to increase their output by about 100-fold, particularly in the UV region where, in general, the light is most needed and the lamp output is weakest. Xenon lamps are not very stable in the millisecond or higher timescale region because of arc instability. For experiments in this time domain, tungsten-halogen lamps for the visible region [118] and deuterium lamps in the UV region [119] are convenient.

A shutter and cutoff filters are usually placed between the light source and the irradiation cell to minimize photolysis effects. For example, when the MV^{2+} /formate dosimeter is used (see Table 8), it is essential to exclude UV light to prevent photolytic generation of $\text{MV}^{\bullet+}$, which is also the product of this dosimeter system. Similar considerations apply to the ferrocyanide and Fricke dosimeters where photo-oxidation of Fe^{II} to Fe^{III} can occur. Different filters are sometimes mounted on a wheel that can be remotely controlled, possibly by a computer, as it is done for the shutter.

By means of lenses and mirrors, the monitoring light is transported through a hole in the shielding wall from the accelerator room into the control room, and focused onto the entrance slit of a monochromator. Two monochromators and appropriate filters are usually used to minimize the amount of scattered light that could reach the photodetector. The setting of the monochromator(s) and the in/out positioning of the filters can be computer-controlled. The light emerging from the monochromator is transformed by the photodetector (photomultiplier or photodiode) into an electrical signal which, after amplification, is gathered by a transient recorder (oscilloscope or transient digitizer) as a set of voltage-time values which are fed into the computer. In general, a so-called back-off circuit is used, which reduces to zero the large voltage generated by the high level of the continuous analyzing light, and so allows the measurement of small transient or permanent changes in light intensity superimposed on it.

Photomultipliers and photodiodes are used in the UV-Vis and in the NIR-IR regions, respectively. In general, the optical system comprises different interchangeable boxes containing different photomultipliers or photodiodes so that a wide spectral range can be covered. The response time and the sensitivity of a photodetector can be varied by appropriate changes in the electronic circuits; this can generate

“fast, low-sensitivity” and “slow, high-sensitivity” interchangeable boxes. Details on the optical monitoring techniques for transient species [125] and back-off circuits [125, 126] are available in the literature.

The optical detection system is effectively a spectrophotometer and the following should be checked regularly to ensure that it is working correctly:

- 1) The photodetector response should be linear, that is, the output current i of the detector should be proportional to the incident light intensity I ;
- 2) The wavelength settings on the monochromator(s) should be correct;
- 3) The widths of the entrance and exit slits of the monochromator(s), which determine the optical bandwidth ($\pm\delta\lambda$) at a given wavelength λ should be narrow compared to the width of the spectral features. Absorption coefficients of narrow peaks measured with too large slit widths will be too small;
- 4) The response time of the electronics should be much shorter than the time dependence of the chemical species of interest.

In many laboratories, pulse radiolysis has become, similarly to laser flash photolysis, a “one-button” operation [127]. This means that the majority of the experimental parameters are entered into the computer before the command to trigger the pulse is given. Thus, the computer will perform a number of operations such as setting the accelerator and the monochromator(s), inserting the required filters, changing the solution in the irradiation cell, resetting the monitors of the light level, dose, and temperature, triggering the lamp, opening the shutter, triggering the back-off unit and the recorder, and, finally, triggering a pulse from the accelerator. In the case of signal averaging at a fixed wavelength, these operations will be automatically repeated for a predetermined number of times, and it is important for second-order decay kinetics that the dose per pulse is kept constant during the averaging process. For running a spectrum, the initial and the final wavelengths, as well as the wavelength increment and the number of observations at each wavelength, are also entered into the computer. At the end of the experiment, a file or a set of files will be stored in the computer together with any required parameters and other information. From these files, traces representing absorbance versus time (fixed wavelength experiment) or absorption spectra as a function of time (multiwavelength experiment) will be obtained. Examples of traces and a spectrum are shown in Figure 7 and will be discussed in Section 3.10.

The pulse radiolysis setup shown in Figure 3 also represents the situation where emission from a transient species is to be measured. Under these circumstances, the monitoring light beam is unnecessary, but the optical system usually requires some adjustments in order to increase the amount of emitted light that can be transported from the sample cell onto the photodetector. A classic pulse-radiolysis-induced emission experiment is represented by Eq. 62 and is described in Section 3.6.1 (under “General chemistry”). Another example is the observation of luminescence at 1.27 μm from singlet oxygen, $\text{O}_2(^1\Delta_g)$, generated by energy transfer from the triplet excited state of benzene (68) [128]:

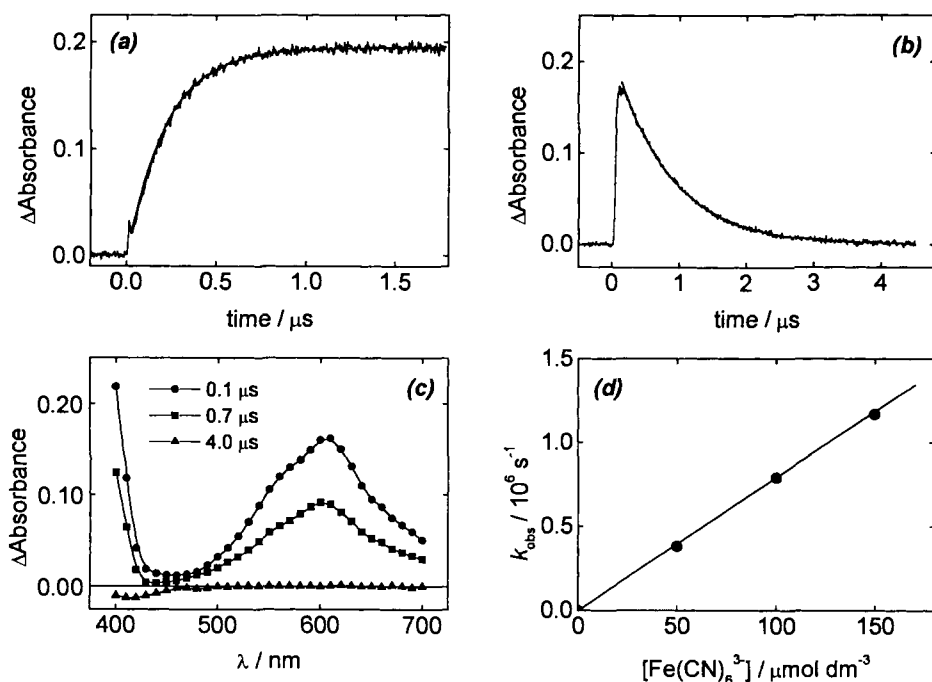

Figure 7. Examples of data obtained by pulse radiolysis with optical detection. a) Formation of $\text{MV}^{\bullet+}$ from the reaction of MV^{2+} with $\text{CO}_2^{\bullet-}$ in N_2O -saturated solution containing $5 \times 10^{-4} \text{ mol dm}^{-3} \text{ MV}^{2+}$ and $0.1 \text{ mol dm}^{-3} \text{ HCO}_2^-$. Conditions: optical path = 2.0 cm, $\lambda_{\text{mon}} = 605 \text{ nm}$, dose = 10 Gy (10-ns pulse). b) Decay of $\text{MV}^{\bullet+}$ obtained in N_2O -saturated solution containing $5 \times 10^{-3} \text{ mol dm}^{-3} \text{ MV}^{2+}$, $0.1 \text{ mol dm}^{-3} \text{ HCO}_2^-$ and $1.5 \times 10^{-4} \text{ mol dm}^{-3} \text{ Fe}(\text{CN})_6^{3-}$. Conditions same as in (a). c) Spectral changes obtained from the pulse irradiation of solution (b). Conditions same as in (a). d) Plot of k_{obs} vs $[\text{Fe}(\text{CN})_6^{3-}]$ for the decay of $\text{MV}^{\bullet+}$ obtained from the pulse radiolysis of N_2O -saturated solutions containing $0.1 \text{ mol dm}^{-3} \text{ HCO}_2^-$ and $5 \times 10^{-3} \text{ mol dm}^{-3} \text{ MV}^{2+}$. Conditions same as in (a).

In this case, a 7-m optic fiber was used for coupling the reaction cell and the photodetector.

Light-scattering measurements

Time-resolved measurements of the intensity of scattered light (Rayleigh or Raman) require the use of a sample cell with optical windows at each end and on one of its sides, together with a monochromatic analyzing light source, which is generally a laser. In the case of Rayleigh scattering, for example, by polymer molecules such as polynucleotides, it is convenient to use the 514.5-nm line from an Ar ion laser [129]. The configuration of the cell is such that the analyzing light beam crosses the sample perpendicularly to the electron beam and the light scattered is monitored at 90° to the laser beam and the electron beam by an optical system analogous to that used

for absorption/emission measurements [129]. A similar cell configuration is used for time-resolved resonance Raman spectroscopy [90, 130]. In this case the analyzing light source is usually a tunable dye laser emitting light at a wavelength within the absorption band of the transient species under examination and the detector is an optical multichannel analyzer (OMA). In each case, kinetic information is obtained from variations in the intensity of the scattered light with time. Furthermore, time-resolved resonance Raman spectroscopy can reveal mechanistic details that are not observable by absorption spectroscopy. For example, it has been shown recently [131] that a direct electron-transfer path occurs in the reaction of $\cdot\text{OH}$ with selected aromatic molecules in aqueous solution, the extent of this pathway, as opposed to addition of $\cdot\text{OH}$ to the benzene ring, being directly related to the ionization potential (IP) of the molecule. If $\text{IP} > 8 \text{ eV}$, addition is the first step, and if $\text{IP} < 7 \text{ eV}$, it is electron transfer, with both processes occurring at intermediate values of IP [131].

Conductivity measurements

The scheme shown in Figure 3 also describes the case in which optical and conductometric detection (see below) are carried out simultaneously. In the most simple arrangement, the sample cell is provided with two parallel electrodes, usually of platinum or glassy carbon which define the volume of solution that is irradiated by the electron beam and interrogated by the monitoring light beam [132]. Except for the electrodes, the cell and the flow system are essentially the same as those used for performing optical measurements. The electrical signals originating from the respective changes in conductivity and absorption, induced by the irradiation of the system, are captured by the transient recorder and fed into the computer. The final result is the generation of two traces, representing the respective time-dependence characteristics of absorbance and conductivity.

There are two conductometric methods, D.C. and A.C. In the D.C. method a constant voltage, typically in the range 100–300 V [124] is applied between the electrodes, and the conductivity is recorded as a function of time. To avoid electrolysis and polarization of the electrodes, the polarity of the applied voltage is usually reversed at a frequency of 10–100 Hz [121]. The D.C. method can be used to cover the time range 10 ns to 100 μs with intrinsic solution conductances of up to $5 \times 10^{-4} \text{ S cm}^{-1}$, that is, the solution should not contain more than about $10^{-3} \text{ mol dm}^{-3}$ of ion pairs. Higher concentrations can be tolerated for shorter time ranges, the limiting factor being baseline drift due to the intrinsic conductance of the solution.

In the A.C. method, two identical cells are used to form two arms of a Wheatstone bridge powered by an A.C. voltage from a high-frequency (10 MHz) generator [122, 133]. Both cells contain the solution to be investigated but only one of them is irradiated, thus creating a voltage difference in the two arms of the bridge, from which the change in conductance can be obtained. The advantage of the A.C. method is that conductance changes can be measured from a few microseconds to infinite time in solutions containing up to $10^{-2} \text{ mol dm}^{-3}$ ion pairs.

Detailed descriptions of state-of-the-art apparatus and experimental procedures can be found in the literature for D.C. [124] and A.C. [133] conductivity detection.

Dosimetry for conductivity detection

The chemical dosimeter used for pulse radiolysis experiments with optical and conductivity detection is the tetranitromethane (TNM) dosimeter (see Table 8). The reduction of TNM by e_{aq}^- and/or $(CH_3)_2\dot{C}OH$ generates in less than 1 μs the stable nitroform ion $C(NO_2)_3^-$, which absorbs at 350 nm (ϵ 1500 $m^2 mol^{-1}$); $G[C(NO_2)_3^-] = 0.60 \pm 0.02 \mu mol J^{-1}$. The conductivity signal arises from the formation of the $C(NO_2)_3^-/H^+$ ion pair for which the molar conductance Λ is 360 and 390 $S cm^2 mol^{-1}$ at 18 and 25 $^\circ C$, respectively [121–124].

Other calibration systems for conductivity measurements that have been described include the following [134–139]:

- 1) N_2O -saturated $1 \times 10^{-2} mol dm^{-3}$ dimethylsulfoxide (DMSO) at pH 4–5 for which $G(H^+) = G(CH_3SO_2^-) = 0.62 \mu mol J^{-1}$ and $\Lambda(H^+/CH_3SO_2^-) = 350 S cm^2 mol^{-1}$ at 18 $^\circ C$ [135].
- 2) O_2 -free $0.1 mol dm^{-3}$ tert-butanol saturated with CH_3Cl at pH 4–5. The conductivity signal is caused by H^+/Cl^- which form with $G = 0.33 \mu mol J^{-1}$ [135].
- 3) $5 \times 10^{-3} mol dm^{-3} CH_2Cl_2$ and $0.2 mol dm^{-3}$ tert-butanol at pH 4.3. The conductance increase is due to the formation of H^+ ($G = 0.28 \mu mol J^{-1}$, $\Lambda = 350 S cm^2 mol^{-1}$) and Cl^- ($G = 0.28 \mu mol J^{-1}$, $\Lambda = 76 S cm^2 mol^{-1}$) [136].
- 4) O_2 -free $2.5 \times 10^{-3} mol dm^{-3}$ acetone, $1 \times 10^{-4} mol dm^{-3} MV^{2+}$, and $0.2 mol dm^{-3}$ tert-butanol at varied pH. The conductance change results from the replacement of MV^{2+} by MV^{+} (which corresponds to $\Lambda = 40 S cm^2 mol^{-1}$) and the formation of one proton in acid solution or the removal of one OH^- ($\Lambda = 200 S cm^2 mol^{-1}$) in basic solution [137].
- 5) $0.1 mol dm^{-3}$ methanol and 0.2 – $0.5 mmol dm^{-3}$ tetranitromethane at pH 4–5 for which $G(H^+) = G(\dot{C}H_2OH) = G(\dot{O}H + H^+) = 0.68 \mu mol J^{-1}$ [138].
- 6) N_2O -saturated $1 \times 10^{-3} mol dm^{-3}$ phenol at pH 11.2 for which $G(OH^-) = 0.62 \mu mol J^{-1}$, assuming a molar conductance for the phenolate ion of $35 S cm^2 mol^{-1}$ [139].

3.8 Other Methods of Detection

3.8.1 Polarography

The principle of this method [140] is to obtain information on electron transfer between the radical and a hanging drop mercury electrode which gives rise to a polarographic current recorded as the change in voltage across a resistor. The electron transfer gives rise to a cathodic (positive) or anodic (negative) current depending on whether the radical is reduced or oxidized as in Eqs. 69 or 70:

In pulse radiolysis experiments the radicals are produced homogeneously in the solution. The polarographic current, i , is determined by the concentration of radicals at the electrode surface, the rate at which they are oxidized or reduced and the rate at which they are replaced by other radicals diffusing to the surface from the bulk solution; account also has to be taken of reactions of the radicals in the bulk solution. By measuring the current, at a fixed time after the pulse, as a function of the potential applied, one can obtain a polarogram which is characteristic of the redox behavior of the radical and so can be used to identify it. Information about the rate of electron transfer can be extracted from measurements of the time dependence of i at a fixed potential. For radicals which undergo self-reaction in the bulk solution, the appropriate relationship is given by Eq. 71, provided the time is shorter than the first half-life of the radical [140],

$$\frac{1}{i_t t^{0.5}} = \frac{\pi^{0.5}}{nFAD^{0.5}c_0} + \frac{2k_2\pi^{0.5}t}{nFAD^{0.5}} \quad (71)$$

where n is the number of electrons transferred, F is the Faraday constant, A is the surface area of the electrode, D is the diffusion coefficient, c_0 is the concentration of radicals at the electrode, and $2k_2$ is the rate constant for the self reaction in the bulk solution.

3.8.2 Microwave Detection

The microwave-detection method has been developed [141] for the study of ionic species and their reactions in nonpolar liquids on a nanosecond timescale, and relies on the fact that microwaves are attenuated in weakly conducting media. It is very useful, for example, for the study of geminate recombination of radical ions in liquid hydrocarbons. It is also more suitable than either optical or D.C. conductivity methods for the study of homogeneous ion recombination processes where problems in data analysis can arise from underlying absorptions and distortion of the kinetics due to separation of the ions, respectively.

Although it is essentially a conductivity technique, the experimental setup is very similar to that used for optical absorption measurements. In simple terms, the attenuation of the amplitude of the microwave resulting from its passage through the irradiated system is measured. Actually, the microwaves are reflected back through the medium by a metal plate at the back of the cell, but because microwaves undergo reflection at any dielectric discontinuity, such as the gas-liquid interface at the front of the cell, interference effects arise due to the coherent nature of the microwave radiation.

The primary information obtained is the transient change in the output voltage of the detector, which occurs when the sample in the cell is made conducting by a pulse of ionizing radiation. The cell is constructed of a length of metal waveguide and can be one of two types: a reflection cell or a resonant-cavity cell. With the reflection cell, microwaves pass from the source through the sample and are reflected from the rear wall of the cell back to the detector. The resonant-cavity cell, on the

other hand, acts effectively as a multiple reflection cell which results in a longer path length through the irradiated medium.

3.8.3 Magnetic Resonance

Electron paramagnetic resonance

An important property of EPR spectroscopy is the detailed information provided by the structure of the spectra so that there is higher degree of certainty of correctly identifying the radicals than is the case with optical spectroscopy. Thus, chemically similar radicals that would be expected to have similar UV absorption spectra have completely different EPR spectra. For example, in its reactions with organic molecules, $\cdot\text{OH}$ can attack at a number of different sites, either to abstract a hydrogen atom from a saturated molecule (see Table 5) or to add to an aromatic ring. Each of the product radicals has a distinctive EPR spectrum, and the relative efficiency with which reaction occurs at each site on the target molecule can be determined from the intensities of the spectra of the various radical products.

Pulse radiolysis allows time-resolved measurements to be made. The radiation pulse is guided through an axial hole in the EPR magnet to generate the radicals directly in a suitable cell located in the EPR cavity. Usually the solution under investigation flows continuously through the cell and optimum sensitivity and time resolution is achieved by repetitive pulsing combined with signal sampling and averaging.

Absorption of microwave radiation occurs when the following resonance condition,

$$h\nu = g_e\mu_B B \quad (72)$$

is fulfilled, where g_e is the magnetogyric ratio, μ_B is the Bohr magneton, and B is the magnetic field strength. Equation 72 applies when the populations of the spin-energy levels conform to the Boltzmann distribution; in time-resolved experiments, however, the transient radicals encounter one another and, depending on their spin states, either react (singlet state) or separate (triplet state), resulting in abnormal line intensities in the EPR spectrum (the equilibrium Boltzmann distribution is not attained). This phenomenon is known as chemically induced dynamic electron polarization or CIDEP.

Two different types of pulsed EPR experiments are possible: a spectrum can be measured at a fixed time after the pulse by variation of the field strength B (Eq. 72), or the time profile of a particular spectral line can be measured at constant B to give kinetic information. One variation of this kinetic method is to detect the recombination of singlet-state radical ion pairs in liquid hydrocarbons by the fluorescence of the product excited state [142]. This technique is known as fluorescence-detected magnetic resonance (FDMR) and provides information on the spin dynamics of the radical ion pair as well as the chemical kinetics.

A second variation, which is extremely useful for measuring rate constants of hydrogen atom reactions in aqueous solution, is the following: immediately after

formation of H^\bullet in the EPR cavity by radiolysis, a $\pi/2$ microwave pulse is applied and the subsequent free induction decay (FID) is recorded [143]. The information extracted from the FID signal includes the rate of scavenging of H^\bullet by the solute and any spin exchange and chemical reactions between H^\bullet and other radicals. These latter processes are second-order in radical concentration and can be minimized by the use of small radiation doses. The FID method, as applied to reactions of the hydrogen atom in water, has distinct advantages over optical detection for the following reasons. First, the absorption spectrum of H^\bullet is in a generally inaccessible region of the UV [56], and secondly, $G(\text{H}^\bullet)$ in neutral water is only $0.062 \mu\text{mol J}^{-1}$, so that the optical signals in any case tend to be rather weak.

Nuclear magnetic resonance

This method has been developed and used at the Argonne National Laboratory [144]. It is used to measure the chemically induced dynamic nuclear polarization (CIDNP) of the products of radical reactions. Because the separations of the energy levels of the nuclear spin states are a thousand times smaller than those of electron spin states, a very homogeneous magnetic field is required to detect them. It is not possible, therefore, to have an axial hole in the NMR magnet to measure the NMR signal directly inside the irradiation cell. Instead, the radicals are generated by irradiation through an axial hole in a small magnet and are then transferred by a fast flow system to the probe of the NMR spectrometer. Although the radicals will have reacted by then, any CIDNP resulting from their reactions will be contained in the products as long as the solution can be transferred to the spectrometer before nuclear spin relaxation occurs. In practice, this means that a transfer time not longer than one or two seconds is required.

3.9 Picosecond Pulse Radiolysis

Although much valuable kinetic and mechanistic information has been obtained by pulse radiolysis with pulses of lengths in the nanosecond to microsecond time range since the technique was invented, it was natural to want to achieve even shorter time resolution, for a) the direct observation of the events taking place in the early stages of radiolysis (10^{-14} – 10^{-10} s), such as electron solvation, ion recombination, spur reactions, and so forth, and b) the measurement of very fast reaction rates (see below).

The first pulse radiolysis system capable of picosecond time resolution (20 ps) was in use by 1968 at the University of Toronto [145] and others were subsequently installed at Notre Dame University, Argonne National Laboratory, Tokyo, Osaka, and Hokkaido Universities, the Hahn–Meitner Institute in Berlin, and the Institute of Chemical Kinetics and Combustion in Novosibirsk. Current developments at Brookhaven [104] and Argonne [146] National Laboratories and Tokyo University [147] are aimed at subpicosecond timescales; a new picosecond facility is also being installed at Orsay [148].

The picosecond system at the University of Toronto was based on an *S*-band linac which produced a single 35-ns pulse containing 100 fine-structure pulses of less than 10 ps spaced 350 ps apart [149]. The analyzing light was the Cerenkov radiation generated when the high-energy (40 MeV) electrons from the accelerator passed through air, and the arrival of this light pulse at the sample was delayed with respect to the electron pulse by travelling a longer distance through an optical delay system; both pulses passed coaxially through the sample cell. The delay could be varied so that the absorption signal produced by each fine structure pulse could be measured at different stages of its formation and decay and so a complete absorbance–time profile could be obtained from a train of fine-structure pulses. This stroboscopic method makes it unnecessary for the optical detector to have a particularly fast response. This system allowed a time resolution of 20 ps within the time window of 20–350 ps between one fine structure pulse and the next. However, uncertainty about the age of a primary product arises when the product does not disappear within this time window.

The stroboscopic pulse radiolysis system described above was modified at Argonne National Laboratory to use a single fine-structure pulse from a 20-MeV L-band linac [150]. This reduced the uncertainty in the age of the primary products to the width of a fine-structure pulse and allowed kinetic measurements to be extended to 3.5 ns. In practice, the time resolution of absorbance measurements was 100 ps.

Improvements in time resolution in the stroboscopic method were achieved at the University of Tokyo by use of a twin linac system in which one accelerator delivers the electron pulse to the sample and the other generates the Cerenkov light pulse used as the analyzing light [151]. Both linacs are driven by the same microwave source and delay between the electron pulse and the light pulse is achieved by phase shifters [151a]. The result is that the time interval between these two pulses is less than 3 ps.

The new accelerator at Brookhaven is based on an RF photocathode gun with one or more resonant cavities in which microwaves create transient electric fields up to 1 MeV cm⁻¹ [104]. A pulse of laser light is used for generating photoelectrons which are accelerated to 9 MeV in a distance of 30 cm. The laser pulse can also be used as the analyzing light source; this means it is closely synchronized with the electron pulse. The time resolution of the electron pulse is therefore that of the laser pulse, so that subpicosecond pulse radiolysis is possible. A similar system is planned at Argonne National Laboratory [146].

With optical detection, the overall time resolution is limited by the different velocities of fast electrons and photons in condensed media; this results in loss of synchronization as the two beams pass through the sample cell. This desynchronization is approximately 10 ps cm⁻¹ in water [145], so the optical path length has to be reduced proportionally to achieve the improved time resolution provided by subpicosecond pulses. There is thus a compromise between having short time resolution (short optical path) and high absorbance signals (long optical path).

One example of fast reaction rates measured with a picosecond system, involving intramolecular electron transfer, has already been described in Section 3.5.5. Another example is the measurement of rate constants of solvated electrons in

water and alcohols at high concentrations of electron acceptors, S [152]. Under these conditions, the yield of e_s^- at the end of a 20-ps pulse is markedly reduced, with $G(e_s^-) \propto -\ln[S]$. The decrease may partly be due to reaction of the electron before it becomes solvated, and partly due to it becoming solvated within the reaction distance of S so that it does not have to diffuse to react. It was found that there was a good correlation between $[S]_{37}$, the value of [S] that reduces $G(e_s^-)$ to 37 % of its value in the absence of S, with the rate constant $k(e_s^- + S)$ measured at high [S] in water, methanol, and ethanol. However, there was very poor correlation with $k(e_{aq}^- + S)$ measured at low [S] in water [152].

3.10 Data Capture and Analysis

As illustrated by Figure 3, it is standard practice in pulse radiolysis experiments to capture analog signals, for example, from photodetectors or conductivity cells, with transient recorders that output these signals in digital form so that they can be fed into a computer for analysis. Of course, the time resolution of the transient digitizer must be compatible with that of the signal of interest. Once the data have been stored in the computer they can be analyzed, either “on-line” whilst the experiment is being carried out or at a later date. Unless the measurements being made are routine ones, it is good practice to carry out some critical on-line analysis to ascertain whether or not the correct experimental conditions have been chosen so that they can, if necessary, be adjusted before a lot of irrelevant data have been acquired.

The computer software used for data analysis comprises programs that are generally written “in-house” for kinetic and spectral analysis, and are developed according to the needs of the experimenters [127a]. Analytic solutions for simple reaction schemes are available [153]. For analysis of complex kinetics involving several reactions occurring simultaneously and/or sequentially, an algorithm such as FACSIMILE [154] can be used to numerically integrate the specified set of differential equations and so enable the time profile of the reactions to be modeled and compared with that observed experimentally. If all the parameters are known for the chosen reaction set, then the time profile can be simulated and the reaction set adjusted to obtain agreement with experiment. On the other hand, if some of the parameters are unknown, they can then be evaluated in a nonlinear least-squares fitting procedure.

The majority of the data analysis required in pulse radiolysis experiments is quite straightforward; this is exemplified in Figure 7 for the absorbance changes obtained from the pulse radiolysis of N_2O -saturated aqueous solutions containing $0.1 \text{ mol dm}^{-3} \text{ HCO}_2^-$, 5×10^{-4} or $5 \times 10^{-3} \text{ mol dm}^{-3} \text{ MV}^{2+}$, $0\text{--}1.5 \times 10^{-4} \text{ mol dm}^{-3} \text{ Fe(CN)}_6^{3-}$, and ionic strength $\mu = 0.1 \text{ mol dm}^{-3}$. Panel (a) shows $\text{MV}^{\bullet+}$, formed in the reaction shown in Eq. 73, and monitored at 605 nm:

The displayed signal is the average of three oscilloscope traces and the solid line shows the first-order kinetic fit to the data. Under these conditions, $MV^{•+}$ is infinitely stable and the absorbance at the plateau can be used to measure the dose-taking $G\varepsilon(MV^{•+}) = 9.66 \times 10^{-4} \text{ m}^2 \text{ J}^{-1}$ [118]. The small spike at the end of the pulse is real and is due to e_{aq}^- which disappears rapidly upon reaction with N_2O [7a]. Panel (b) shows the decay of $MV^{•+}$ at 605 nm in the presence of $1.5 \times 10^{-4} \text{ mol dm}^{-3} \text{ Fe(CN)}_6^{3-}$ as a result of the reaction shown in Eq. 74:

The displayed signal is the average of five traces and the solid line shows the first-order kinetic fit to the data. Note the rounding off of the signal at short times because of simultaneous occurrence of the reactions of Eqs. 73 and 74. The rate constant for the reduction of ferricyanide by $\text{CO}_2^{•-}$ is $k = 7 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at $\mu = 0.1 \text{ mol dm}^{-3}$ [7a] so that, under these conditions, more than 97 % of $\text{CO}_2^{•-}$ reacts with MV^{2+} . Panel (c) shows the spectral changes observed when $[MV^{2+}] = 5 \times 10^{-3} \text{ mol dm}^{-3}$ and $[\text{Fe(CN)}_6^{3-}] = 1.5 \times 10^{-4} \text{ mol dm}^{-3}$ as the reactions in Eqs. 73 and 74 take place. The spectra at 0.1 and 0.7 μs are undoubtedly due to $MV^{•+}$ as it decays (Eq. 74), whilst the spectrum at 4 μs shows an increase of transmission in the region of 420 nm due to the removal of Fe(CN)_6^{3-} (λ_{max} 420 nm, ε_{max} 102 $\text{m}^2 \text{ mol}^{-1}$) [9] by Eq. 74. The absorbances of Fe(CN)_6^{4-} and MV^{2+} are negligible above 400 nm, so that the decay to the baseline in panel (b) is to be expected. Finally, panel (d) shows a plot of k_{obs} for Eq. 74 against $[\text{Fe(CN)}_6^{3-}]$, the slope of which gives $k_{3,74} = (7.8 \pm 0.1) \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at $\mu = 0.1 \text{ mol dm}^{-3}$. The zero intercept confirms that Eq. 74 accounts for all $MV^{•+}$.

In some cases, it is necessary to establish whether the product(s) originating from the reaction of a given radical with the solute under investigation possesses oxidizing or reducing properties and/or whether the reaction is quantitative or not. This can be done by means of so-called redox indicators, that is, species that, when acting as electron donors or acceptors, generate products that can be easily monitored and quantified. A number of redox indicators and their properties are presented in Table 9. A recent example [156] of this practice is represented by the examination of the redox properties of the product originating from the reaction of 8-bromoguanosine (8-Br-Guo) with e_{aq}^- at $\text{pH} \approx 7$; this substance was unreactive towards MV^{2+} , but generated $\text{TMPD}^{•+}$ from TMPD in nearly quantitative yield. This finding contributed substantially to the definition of the mechanism of reduction of 8-Br-Guo.

3.11 Purification of Materials and Preparation of Solutions

Purity of solvents, solutes and gases is important in pulse radiolysis experiments because very reactive species are generated in micromolar concentrations in solutions that may be saturated with a gas and contain up to molar concentrations of

Table 9. Selected redox indicators for pulse radiolysis studies with optical detection.

Compound	Monitored species	λ_{mon} [nm] (ϵ [$\text{m}^2 \text{mol}^{-1}$])	Redox potential E° (A/A ⁻) [V]
Electron acceptors, A			
C(NO ₂) ₄	C(NO ₂) ₃ ⁻	350 (1460) ^a	>0.16 ^b
Fe(CN) ₆ ³⁻	Fe(CN) ₆ ³⁻ (bleaching)	420 (102) ^c	0.36 ^d
MV ²⁺	MV ^{•+}	606 (1370) ^e 396 (4210) ^e	-0.45 ^f

scavengers, acid, alkali, buffers to control pH, and neutral salts to control ionic strength. Most commercially available gases and chemicals solutes are of sufficient quality that they can, in many cases, be used without further purification. It is important, however, to vary the concentrations of these solutes, either a) to confirm that the reactions of interest are not affected by adventitious impurities, or b) to quantify these effects so that appropriate corrections can be made. If, for example, the additive (scavenger, buffer, etc.) is 99.5 % pure, the amount of X, where X represents a generic impurity, introduced into the system could reach levels as high as millimolar, that is, comparable to, or even higher than the concentration of the solute S under investigation.

3.11.1 Purification of Solvents

The principal method of purifying solvents is by distillation under conditions where oxidizable and reducible impurities are removed. Of course, the purified solvent should not then be exposed to a polluted atmosphere or contaminated glassware; organic solvents are generally kept in an inert atmosphere after purification. One commonly used test for solvent purity is to measure the lifetime of the solvated electron in it following a small pulse of radiation. For example, the lifetime of e_s^- in the solvent system should be significantly longer than in the solution in which its reaction rate is being measured, and this condition determines the necessary level of purity. Thus, less pure solvents can be tolerated, for example, in picosecond pulse radiolysis where timescales are short compared to the time of reaction with the impurity.

Water

Nowadays water is generally purified by means of commercially available purification systems and this is adequate for most work in radiation chemistry. Previously, it was common practice to carry out triple distillation, in which distilled water was redistilled successively from alkaline permanganate and acidic dichromate solutions; in some laboratories the steam was passed through a silica tube heated to 800 °C before being condensed [157].

Nonaqueous solvents

Here the purpose of purification is to remove water as well as other impurities. In general, the degree of purity required depends on the conditions of the experiment; thus, the most stringent purification procedures should be adopted when radiation effects are measured in the solvent alone, but these precautions may not be necessary when solutes are to be added. The various methods for purification of these solvents are illustrated by the following specific examples taken from the literature.

- 1) Alcohols were refluxed over sodium metal and NaBH_4 , fractionally distilled and stored under argon [11a, 158]. Alternatively, they were refluxed with 2,4-dinitrophenylhydrazine and H_2SO_4 for 15 h and then distilled twice under argon [12b].
- 2) Acetonitrile was passed through a 2-m column of type-H activated alumina, refluxed for 48 h, and then fractionally distilled [21b].
- 3) Acetone was distilled from KMnO_4 and dried over molecular sieves [19].
- 4) Chlorinated hydrocarbons were washed successively with concentrated H_2SO_4 and KOH followed by distilled water, dried over barium oxide and passed through a column of alumina [26, 27].
- 5) Cyclohexane was passed through a 1-m column of activated silica gel and stored under argon [32]. Alternatively, it was bubbled with argon, shaken first with concentrated H_2SO_4 , then with KOH pellets and finally stirred over Na/K alloy under vacuum for several days [159].
- 6) Ammonia was treated with Na/K alloy and then distilled under vacuum [73].

Gases

The purity of commercially available gases is such that most can be used straight from the cylinder, but where it is essential to remove O_2 , for example, from N_2O , this can be done by passing the gas through a column of Cr^{2+} solution [160] or one of the commercially available gas purifiers. Even then it is important to know whether a solution that is required to be free of oxygen really is that. An easy test, which permits the amount of oxygen that is left in the solution after the purging procedure to be quantified, is performed by pulsing of an N_2O -saturated or any inert gas purged solution containing $5 \times 10^{-4} \text{ mol dm}^{-3} MV^{2+}$ and $0.1 \text{ mol dm}^{-3} HCO_2^-$ and then measuring the loss of the resulting MV^{+} radical cation. In the presence of micromolar amounts of O_2 , a decay of MV^{+} is observed in the millisecond time frame. If it is assumed that O_2 is the only species that reacts with MV^{+} , then the concentration of O_2 left in the solution can be calculated from the following stoichiometric equation:

The amount of MV^{+} that is destroyed can be easily calculated from ΔOD at 605 nm, the optical path of the cell, and the extinction coefficient of MV^{+} , $\epsilon_{605} = 1.37 \times 10^3 \text{ m}^2 \text{ mol}^{-1}$ [161].

3.12 Concluding Remarks

In the context of electron-transfer reactions, the contribution to the body of knowledge on the kinetics and mechanisms of these processes from pulse radiolysis studies is very significant. As has been shown above and elsewhere (see the list of "Further Reading"), pulse radiolysis is particularly well suited to the study of fast electron-transfer reactions involving free radicals and metal ions in unusual oxidation states.

Because of the high cost of setting up new pulse-radiolysis facilities, there is a need for the existing facilities to be made more available to the wider chemistry community through expanded collaboration with radiation chemists who have access to them. There is also a need to increase the awareness of the wider chemistry community of the achievements and potential of radiation-chemical methods in general chemistry; such awareness is likely to develop only by the introduction of radiation chemistry into the chemistry curriculum in higher education.

4 Photochemical Techniques

Kevin Henbest and Michael A. J. Rodgers

4.1 Introduction

The advantages of photochemical techniques for initiating electron-transfer reactions and measuring their kinetic features are manifold. Many excellent reviews, research monographs, and specialized books describing photoinduced electron transfer and the photochemical techniques employed have been published, and the reader is referred to them throughout this review [1–11]. In this chapter, a summary of basic principles and standard techniques is given and attention is paid to the several applications and to the limitations of the various techniques. The current availability of laser excitation sources with short duration pulses coupled with high-time-resolution diagnostic instrumentation enables the experimenter to study a large variety of photoinduced processes occurring over a wide range of timescales. There is no doubt that in the past three decades the photosciences have provided powerful and varied methods for studying electron-transfer processes and have contributed greatly to the development of the area.

An electron-transfer process can be generally represented by Eq. 1:

The reactant state is converted to the product state by the transfer of one electron. The participants in the reactant state may be individual molecules held transiently in proximity by a solvent cage; or they can be distinct parts of a supramolecular unit. Several types of chemical species can make up the reactant state; it may contain only ground-state, spin-paired entities, or electronically excited entities (singlet or other multiplicity), or reactive entities (free radicals, metal complexes in unusual oxidation states, etc.) Many combinations are possible, and a large variety of reactant states can be prepared from some precursor state by photon absorption. The chapters in this series of volumes contain an abundance of examples. In every case, however, no matter what the identity of the entities participating in the process, the

primary challenge to the investigator is to generate the desired reactant state and to measure the rate constant of the electron-transfer event within that framework. Having achieved this, the next challenge is to examine how the rate constant varies with changes in various parameters, such as molecular structure, driving force, spatial separation, orientation, solvent properties, temperature, and so forth. In this way the experimentalist builds up an array of rate data that allows testing of current theories and the formulation of new ones.

It is worth mentioning at this juncture that in a bimolecular reaction between a pair of individual reactive species in dilute homogeneous solution, the desired reactant state is achieved by normal diffusive processes. Except in those cases where there is a large energy barrier to the movement of the electron, the diffusive process itself is likely to determine the overall reaction rate constant. In those cases, the measured rate parameters provide no information on the nature of the electron transfer. The act of obtaining the proper reactive state that allows useful data to be obtained about the electron jump has proven to be a challenge of significant proportions and successful achievement of this has tested the ingenuity of the community of experimental chemists.

4.2 The Significance of Photoexcitation for Electron Transfer

The annihilation of a photon of light in an interaction with the bound electrons of a molecular system induces an electric-dipole transition with the result that a new electronic state is populated. The electronic configuration of the new state is different from that of the original (ground) state configuration, with the result that it possesses chemical properties that are different from the initial one. Energies ranging from 4.95 eV (114 kcal mol⁻¹) for 250 nm light to 1.65 eV (38 kcal mol⁻¹) for 750 nm light can be imparted to molecular arrangements by the straightforward act of light absorption. Thus, the electromagnetic energy of the photon raises the chemical potential of the absorber by amounts that are significant with respect to the energy requirements of many chemical events, including bond breakage. These energetic electronic states are intrinsically unstable and they seek to rid themselves of the excess energy. The ways to do this are diverse. Depending on the nature of the molecule itself and on the other molecules in the vicinity, reactions such as bond fission, bond formation, bond isomerization, excitation transfer, proton transfer, and electron transfer all become potential channels for energy loss. These chemical modes are in addition to the radiative (fluorescence, phosphorescence) and non-radiative deactivation channels. It is this diversity of energy-loss mechanisms that provides the richness of the photochemical sciences; photoexcitation provides a plethora of new chemical entities, the nature and reactivity of which serve to generate a great deal of intrinsic interest and research activity.

Not only does the act of photoexcitation generate interesting chemical entities; it does so with great rapidity. The duration of a single excitation event is a difficult concept to pin down because it is shrouded in the uncertainty principle. However, a

simple calculation shows that a single cycle of 300-nm light (travelling at $3 \times 10^8 \text{ ms}^{-1}$) will pass a point in space in 1 fs. If there happens to be a chromophoric residue (alkene, carbonyl) occupying that point in space, then the annihilation event might take that length of time. On the other hand if annihilation does not require the passage of a full cycle, it will occur in a correspondingly shorter time. In any case, the excitation event is intrinsically very rapid and presents little in the way of “dead time” to an experimental examination of the chemical effects of photoexcitation. The same considerations apply when light is employed to probe the consequences of photoexcitation, such as in optical absorption spectrometry and spectrofluorimetry. Again, the molecule–photon interaction time is vanishingly small and in itself imposes no instrumental time response. As will be examined later, more practical considerations such as the width of light pulses or the impedance of electronic components are the important factors that limit the investigator’s ability to obtain the desired information.

In the context of electron-transfer reactions, photoexcitation has played and continues to play a significant role. The chapters of this series of volumes contain a multitude of examples of the use of photon absorption to initiate reactions in which electrons are transferred from one molecular entity to another. The mission of the current chapter is not to exemplify the uses of photoexcitation in electron-transfer science, but to give some insight into the questions “why use photoexcitation” and “how is it best done?”

4.2.1 Advantages of Photoexcitation

There are several reasons why photoexcitation is employed in the pursuit of knowledge in the electron-transfer arena. Four of these are examined in the following segments.

Energetic considerations

Photoexcitation is able to provide the energy to drive the process in the desired direction. For example, in the schematic process

which is a slightly less generic description than was shown in Eq. 1 and where D and A represent the individual electron-donor and -acceptor species in the reactant state and the “ox” and “red” subscripts indicate the entities having undergone an electron-transfer reaction, the reaction will proceed spontaneously in the indicated direction if

$$E_{A/A_{\text{red}}} - E_{D_{\text{ox}}/D} > 0 \quad (3)$$

where the E quantities represent the one-electron reduction potentials (in volts) of the participants. Were the above inequality not true, then the indicated reaction would be difficult, at best. Suppose, however, that A (or D) is promoted to an

Figure 1. Schematic energy level diagram for a typical photoinduced electron transfer. Charge separation and recombination routes are shown—see text.

(unspecified) excited state by photon absorption:

Such an act provides a source of potential energy that may overcome the thermodynamic barrier of the reaction in Eq. 2, and the appropriate form of Eq. 3 is now

$$E_{A/A_{\text{red}}} + E_{00} - E_{D_{\text{ox}}/D} > 0 \quad (5)$$

Where E_{00} represents the energy of the unspecified excited state of A.

Excited-state energies are upwards of 1.5 eV above the ground state and thus it is clear that the act of photoexcitation will make a major change in the thermodynamic balance. Even significant barriers to reactions in the ground state can be overcome by photoexcitation. This situation is shown schematically in Figure 1, where it can be seen that the redox-pair product state ($D_{\text{ox}}:A_{\text{red}}$) is at an energy level that is intermediate between that of $D:A$ and $D^*:A$.

Thus, from the state $D^*:A$ the electron transfer is energetically downhill and will proceed spontaneously, as will the reaction that regenerates the ground state $D:A$. The use of light to provide the energy requirement for the reaction allows the two-electron-transfer rate constants for each reaction pair to be measured.

The scheme indicated in Figure 1 (excitation, charge separation, charge recombination) is most likely to occur when the product state has the same spin multiplicity as the reactant state, or when the product species are held together (e.g., by chemical bonds) for periods that allow intersystem crossing to occur. However, the charge separation–recombination sequence is not the only type of process that photoexcitation can achieve. An example is when the product state is held only loosely by a solvent cage and the entities therein can diffuse apart and have independent reactive identities. Such a scheme would be typified by the sequence

Here Eq. 6 represents a photoinduced charge-separation process where the product state escapes the cage prior to (or in competition with) recombination. Equation 7 shows a schematic redox reaction involving a substrate S and one of the released components of the product state. This type of sequence uses photons to prepare a redox-active species that is not an excited state of the light-absorbing component.

Control of process

A second good reason for the use of photoexcitation as a means of promoting an electron-transfer process is that it provides the opportunity for the experimenter to prepare the system looked at without any possibility that the reaction being studied will *proceed* during the preparation stage. In the chapter "Classical Methods" in this volume, Bakac points out that the time taken for the reactants to mix can be a limiting factor for rate measurements and she discusses methodologies that have been developed to minimize such problems. Photoexcitation completely circumvents this difficulty because it is not the reactants themselves that are mixed in the reaction vessel, but their ground state precursors. For example, in studies of the photoinduced electron-transfer reactions within electrostatically bound ion-pair complexes in solution, the participating ionic species that were mixed in the reaction vessel to prepare the ion pairs were energetically incapable of undergoing electron transfer [12, 13]. Subsequent photoexcitation generated an excited state of one of the components of the complex, thereby providing the driving force for the desired reaction to proceed. In this way, the sample-preparation stage can be cleanly and completely separated from the reaction stage. No electron transfer can occur until the photons have been delivered and absorbed.

Wavelength variability

Yet another reason for using of light to promote the target reaction is that it allows the wavelength to be employed as a variable parameter. A simple example of this could be applied to the schematic Eq. 2, where either A or D could serve as the absorber of radiation, for example, at different wavelengths. By this expedient, the direction of electron transfer could be reversed. This idea of using variable wavelengths can be made more complicated inasmuch as it allows delayed two-color experiments. Thus, one pulse would prepare an excited state of a precursor compound and, some time later, within the excited-state lifetime, a second color pulse would be injected to convert the primary product into a derivative state (higher excited state, free radical, etc.) This would be one of the reactants in an electron-transfer reaction with another (unexcited) compound present in the reaction mixture. Clearly the imaginative use of wavelength as a variable allows the possibility of investigating unusual situations.

Vast time window

A fourth advantage of using photoexcitation to study electron-transfer reactions is the vast time window that such a technique offers. As has been indicated above, understanding the nature of the electron transfer process relies on the measurement

of rate parameters under controlled conditions. Thus, any methodology that extends the time window in which reaction rates can be studied will be advantageous. As discussed earlier, photon–molecule interactions are to all intents and purposes “instantaneous”. The present state of technology allows the experimenter to generate reactant states and product states and to record their optical signatures on sub-picosecond timescales, a fact that allows reactions occurring with lifetimes less than 10^{-14} s to be kinetically characterized.

The tremendous progress in electro-optic technology over the past 25 years has been an important enabling force that has allowed students of kinetics to explore time domains hitherto existing only in their imaginations. Readers interested in following technological developments as they occur might wish to obtain free subscriptions to trade publications such as “Laser Focus World,” “Lasers and Optronics,” and “Photonics.” The pages therein point the way to the future in photoscience.

4.3 The Methodology of Photokinetics

From the foregoing discussion it is now possible to extend the generalized electron-transfer reaction of Eq. 1 to add a light-induced process:

Where the precursor state is prepared initially by the experimenter by synthesis, mixing, and so forth in the absence of the initiating photons. The conversion of the precursor state to the reactant state is brought about by the absorption of a photon in a chromophore that is part of the precursor state. With the appropriate reactant state being thus prepared, the electron-transfer process will proceed spontaneously at a rate determined by the nature of the reaction. The experimenter’s task is simply to evaluate the rate constant of the elementary reaction that generates the product state. This is accomplished by the time-honored procedure of chemical reaction kinetics, that is, by determining the decrease in concentration of one of the reactant-state components as a function of time, or by determining the increase in concentration of one of the product-state components as a function of time. When the reaction is elementary, that is, when the reactant and product states are coupled through a transition state only, the rates of reactant decrease and product increase convey the same information, namely, the rate constant for the reaction.

There is an important proviso, however, which is that the outlined procedure will only provide the rate constant being sought if there are no competing channels that can also serve to deactivate the reactant state. If the prepared reactant state can also involve itself in a proton-transfer reaction, say, that yields a different product state, then the measured rate constant will be the sum of the rate constants of the two competing processes. The measured rate constant will only be identical to the electron-transfer rate constant if the competing side channels contribute negligibly to the total. It is never good practice to assume without evidence that the electron-

transfer process is the unique reaction path; it is always prudent to measure the stoichiometry of the electron-transfer reaction as well as the rate constant. This problem is even more significant when the rate of decrease of a reactant is the sole observable that is employed to evaluate the rate parameter, as is usually the case when emission lifetimes/quantum yields are employed to monitor the progress of a reaction. That the emission of a donor (say) excited state is quenched in the presence of a putative acceptor is a necessary but far from sufficient condition that the process causing the loss of the emissive state is an electron-transfer event.

4.3.1 Instrumentation Considerations

Having set the scene as to why the approaches of photochemical science are useful in obtaining the kinetic parameters of electron-transfer reactions and having pointed out some cautions, it remains to discuss the “nuts and bolts” of instrumentation and technology. The organization of the remainder of the chapter is that excitation sources will be discussed in a separate segment, since all photomethods largely depend on the same sources. Subsequently, the diverse methods of measuring the time profiles of declining reactant concentrations and growing product concentrations will be outlined.

4.3.2 Excitation Sources

Today the very large majority of investigations into the kinetics of electron transfer reactions employ pulsed excitation sources of one kind or another. This is largely because such sources enable a clear distinction to be made between the preparation stage and the reaction stage; they also allow elementary reactions to be followed. This is usually not the case with cw light sources. By their very nature, such sources allow the experimenter to measure loss of starting material and/or formation of a product. To convert such data into information that is relevant to elementary reactions requires mechanistic interpretations that could be fraught with uncertainty. In what follows, the discussion will be restricted to pulsed light sources. For investigators who are interested in cw light sources, an excellent review exists [14].

Pulsed excitation sources

Pulsed flashlamps

The earliest experiments in transient spectrometry used high-energy flashlamps as light sources for generating observable concentrations of short-lived species [15]. Their continued use during the 1950s and 1960s enabled the flash-photolysis technique to be used to great effect in the study of photochemically generated intermediate species [16]. However, flashlamps had their drawbacks. Pulses of useful energy were long in duration ($>1\ \mu\text{s}$), much of the input electrical energy was used for generating light at wavelengths that were not useful in the photochemical study, and the coupling of the light to the sample was difficult and resulted in many losses.

Thus, in the late 1960s, the advent of high-power, short-pulse lasers provided many advantages to the experimentalist and created a revolution in the photosciences.

Pulsed lasers [17]

With the invention of the laser in 1960 [18], and the subsequent development of pulsed lasers using Q-switching methodology, monochromatic and highly collimated light sources became available with pulse durations in the nanosecond regime. Such light sources rapidly gained popularity with photoscientists, because the collimation allowed efficient coupling to the sample, and the monochromaticity property meant that many more photons were available to pump a particular absorption band of the sample at a much lower input energy. The early pulsed lasers allowed the study of photoprocesses that occurred in nanoseconds—some 10^3 times faster than events measurable by flash photolysis with the aid of flashlamps.

It is the process of Q-switching that is responsible for the generation of controlled high-energy laser pulses of a few nanoseconds duration. In this action, the laser medium (solid crystal, gas, or liquid dye) is pumped by a flash lamp with the cavity completely closed (high Q value) so that the medium stores all the input energy and the population of lasing states builds up to a high value. At an appropriate moment during the pumping flash, the cavity is caused to drastically lower its Q value (Q is switched from high to low) and the stored energy is dumped out of the cavity as a giant, short pulse. The sequence of pumping and switching is repeated to generate another pulse, and so on. In modern laser systems, this cycle can be repeated at kHz rates, depending on the energy per pulse required. These days, the Q-switching process is usually achieved by rapidly switching the way in which the cavity transmits polarized light via a Pockels cell. Because Q-switching employs high-voltage electrical pulses to operate the Pockels cell, there is a limiting rate at which this can be achieved, because of circuit rise time characteristics (RC time constants). Q-switched pulse durations of a few nanoseconds are readily available in the year 2000.

A laser excitation source that is employed in many laboratories for nanosecond photolysis studies is the Q-switched Nd:YAG laser [19–21]. The lasing medium is an yttrium aluminum garnet crystal into which Nd^{++} ions are doped. This device typically has a pulse width of 6 ns and lases at its fundamental wavelength of 1064 nm. Output energies per pulse from the oscillator-only configuration can be as high as 0.5 J; this can be increased to multijoule per pulse by amplification. The 1064-nm line can be frequency-doubled to 532 nm, tripled to 355 nm, or quadrupled to 266 nm (with concomitant energy lowering) to give useful excitation wavelengths in the visible and ultraviolet. Frequency doubling is achieved by the beam being passed through an orientated crystal of dihydrogen phosphate (KDP) or β -barium borate (BBO) [22]. The Ruby laser [23] (694 nm, second harmonic at 347 nm) is another solid-state system that can be Q-switched and is capable of delivering high pulse energy.

High-energy ultraviolet light pulses in the 20-ns range can be produced by the transverse discharge of transmission lines through tubes containing gases such as nitrogen (337.1 nm) [24] or mixtures of halogens with rare gases (excimers) [25–27]. The XeCl excimer laser, for example, can typically produce 300 mJ of 15–20-ns

pulses at 308 nm. Gas lasers (excimer) and solid-state lasers (Nd:YAG) are commonly used as pump sources for dye lasers [22]. An advantage of dye lasers is that they are tunable to any wavelength from 340 nm to 900 nm with the suitable choice of laser dye. However, a single, specific laser dye has only a narrow lasing wavelength range, typically 20–30 nm, and the changing of wavelengths requires the insertion of a different laser dye into the cuvette and perhaps different optical elements, and subsequent realignment. There are other complications with the use of laser dyes. The dyes have uncertain stability; the Coumarin dyes for the 450-nm range are particularly susceptible to rapid degradation. The dyes are often toxic or carcinogenic, and if allowed to escape into the laboratory are hazardous to the operators. Such difficulties are avoidable by the replacement of the dye lasers with a solid-state alternative; to this end, optical parametric oscillators (OPOs) have recently been introduced [28–29]. These devices, when pumped by the 355-nm harmonic of a Q-switched Nd:YAG laser, can produce narrow-bandwidth, tunable laser wavelengths from 440 nm to the infrared. From these, UV lines can be generated by frequency doubling of the signal and idler outputs.

Mode-locked lasers

To achieve time resolution below a few nanoseconds requires other methods of generating short laser pulses. The typical method is to resort to mode-locking techniques. In a mode-locked laser, the axial modes that oscillate in the laser cavity are forced into phase-lock condition at some points. As the light pulse is propagated back and forth between the reflecting ends of the cavity, interference occurs between the modes. Where the cycles are in phase, interference is constructive and narrow intense pulses are generated; elsewhere the interference is destructive. This produces a train of pulses within the envelope of the pumping flash. The time interval between pulses (τ_p) is given by

$$\tau_p = 2L/c \quad (9)$$

Where L is the cavity length and c is the velocity of light; the τ_p parameter is the cavity round-trip time. The width of the pulse (FWHM) is given approximately by

$$\Delta\tau \cong 1/\Delta\nu_{bw} \quad (10)$$

Where $\Delta\nu_{bw}$ is the total oscillating bandwidth. The shortest pulses are therefore generated by the widest frequency distributions, that is, by arranging for a broad gain bandwidth. Only those frequencies in the emission spectrum of the laser material that can be maintained above the lasing threshold will participate in $\Delta\nu_{bw}$. Dye lasers and some solid-state lasers (titanium–sapphire) have broad spectral outputs and can produce pulse widths significantly lower than 1 ps. Gas lasers have much narrower bandwidths and typically have pulse widths closer to 100 ps. The solid-state Nd:YAG laser is intermediate at near 30 ps.

There are presently many types of lasers that produce short light pulses which have outputs that differ in wavelength, tunability, pulse length, repetition rate, energy

per pulse, average power, and peak power. In a very general way, mode-locked lasers fall into two categories, high repetition rate (about 10^8 Hz), and low repetition rate (less than about 10^3 Hz). The former class is typified by mode-locked cw lasers; the second by flashlamp-pumped solid-state (e.g., Nd:YAG) lasers.

In several laboratories, repetitively mode-locked cw ion (Ar^+ , Kr^+) or solid-state (Nd:YAG) lasers have been employed to synchronously pump dye lasers [30–31]. These latter operate at a repetition rate of close to 80 MHz and can be tuned to generate pulse widths of as short as ca. 1 ps. The dye laser can, if so desired, be acousto-optically cavity-dumped to achieve lower output rates. Dyes of the rhodamine family ($\lambda_{\text{max}} = 590$ nm) are optimally efficient, and average powers of several tens of milliwatts are achievable with high stability over long periods. This represents a few nanojoules per pulse, although in cavity-dumped mode, where energy is stored in the cavity during the dark periods, the per-pulse output energy can exceed 10^{-8} J. Such energies are very low in terms of the instantaneous concentration of excited states that can be produced. For example, the complete absorption of 10 nJ in a volume of 1 mm^3 will convert about 50 nM of the absorber into excited states. Even with differential extinction coefficients of $5 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$, the absorbance change at the excitation wavelength (in a 1-mm path) would be only about 2.5×10^{-4} —a very small absorbance. For this reason, a high degree of signal averaging is required to extract signal from noise, hence the usefulness of a source of high repetition rates and the need for long-term pulse-to-pulse amplitude stability. An improvement on this approach is amplification of the synchronously pumped dye laser output by passing it through a multistage (three or four) dye-amplifier module [32]. The several stages of this latter can be pumped with excimer, Cu vapor, or Q-switched Nd:YAG lasers. In this way, energies of hundreds of microjoules per pulse are attainable at repetition rates in the range 30 to 200 Hz. Advances with Nd:YAG regenerative amplifiers have yielded repetition rates of 1 kHz in the dye-amplifier pump [33].

Flashlamp-pumped solid-state lasers operating at 10–30 Hz are capable of being mode-locked by combination of an active acousto-optic crystal with a passive saturable absorber. In Nd:YAG lasers, this results in pulses of duration as low as 18 ps with output energies (after amplification) of up to 100 mJ per pulse at 1064 nm. Subsequent harmonic generation steps yield pulses at 532 nm, 355 nm, or 266 nm with energies and stability that conveniently provide excitation beams for flash photolysis studies. Shorter pulses than are obtainable from Nd:YAG can be delivered by Nd:(phosphate)glass systems, which have larger $\Delta\nu_{\text{bw}}$ values. Otherwise, short-cavity dye lasers, pumped by the 18-ps 532-nm pulses from a mode-locked Nd:YAG system will produce tunable light of peak energy near 1 mJ, with pulse widths near 6 ps.

The earliest subpicosecond systems incorporated dye laser technology. Shank, Ippen, and their colleagues at the Bell Laboratories [34] were the first to develop mode-locked subpicosecond lasers and to show how to compress pulses to very short values. With the colliding-pulse mode-locked (CPM) laser they achieved reduced pulse widths well into a subpicosecond range. Two approaches based on synchronously pumped dye lasers and colliding pulse dye lasers are commonly employed to produce subpicosecond pulses. These are briefly discussed below.

The fundamental (1064-nm) line of a mode-locked cw Nd:YAG laser is of intrinsically shorter time duration (about 70 ps) than is the pulse from a mode-locked cw ion laser (>100 ps). Thus, compression of Nd:YAG pulses will achieve shorter pulses for dye pumping. Pulse compression can be achieved by the focusing of the 1064-nm line into a single-mode, optic fiber that imparts frequency chirp to the light [35–36]. Removing this chirp, with a pair of gratings, results in a markedly compressed pulse. Pulses treated in this way, followed by frequency doubling, have yielded 532-nm pulses as short as 6 ps. The pulses can be used to synchronously pump dye lasers, and have generated dye trains with pulse trains near 200 fs in duration [37], similar pulse widths can be obtained by using the normal-width 532-nm beam and a dye pump, but including a saturable absorber in the dye laser cavity, either in a separate jet system or simply as an additive to the dye laser stream [38]. The shortest pulses have been obtained from colliding-pulse dye lasers that are passively mode-locked. Coupled to optimal cavity design and component selection, these have been shown to generate light pulses of less than 100 fs in duration [39, 40]. Pulse durations less than 10 fs have also been generated [41].

The femtosecond laser systems indicated above produce high-repetition-rate (close to 10^8 Hz) pulse trains with individual pulse energies in the nanojoule range. As such, their main usefulness lies in fluorescence excitation sources. As with the low-energy picosecond pulse trains, dye amplification stages can be applied to enhance pulse energies to hundreds of microjoules [42]. The amplification produces pulse broadening owing to frequency chirp induced in the optical components (lenses, windows, liquids, etc.), through which the pulses must pass. To some extent, this can be offset by the addition of a grating pair stage to compress the pulse, although subjecting such devices to the intense peak powers involved are very likely to cause surface damage. In the late 1980s, the state of the art in terms of intense subpicosecond pulses were attained by hybrid dye-excimer laser systems [43]. These generated 80-fs pulses of 248-nm (KrF) light with energy per pulse in the region of 15 mJ.

In the 1990s, titanium–sapphire (Ti–S) based laser systems became commercially available and are currently in widespread use for subpicosecond pulse generation [44–46]. The Ti–S laser has the advantage that it is a solid-state device with an indefinitely long operational life and replaces the need for flowing laser dyes that degrade with time. The lasers are pumped either with a continuous-wave 7-W argon ion laser at 514 nm, or with a 5-W Nd:YAG diode-pumped solid-state laser, frequency-doubled to 532 nm. The Ti–S laser oscillator has tunable output in the range 750 nm to 840 nm with a maximum at 800 nm. Different optics sets can extend the tuning range. The repetition rate is close to 80 MHz. A Ti–S oscillator undergoes self-mode locking through a self-focusing mechanism; the high intensity of light in the crystal produces refractive-index changes in the crystal, most markedly along the axis of the beam waist. A variable aperture is employed to control the mode-locking mechanism. Self-mode locking circumvents the need for matching the cavity length with that of the pump laser. The output pulse from an oscillator of the above type is typically 80 fs, although shorter pulses are achievable [47, 48]. Should longer pulses be required, additional optics can be employed to generate pulses in the picosecond range [49].

The average power output of a Ti-S oscillator is in the region of 500 mW, which corresponds to a per-pulse energy of a few nanojoules. While not powerful enough for transient absorption studies, oscillators of this type have been employed as sources for fluorescence lifetime work, including two-photon excitation, and for fluorescence upconversion studies [50, 51].

For use in transient absorption studies, the output of the Ti-S oscillator can be amplified with, for example, a Ti-S regenerative amplifier operating at 1 kHz. The final output is then a 1-kHz train of pulses, typically 100 fs in duration, with a per-pulse energy of ca. 1 mJ at 800 nm (or close to it). The amplifier is typically pumped at 1 kHz with the second harmonic (527 nm) of a Q-switched Nd:YLF laser. Prior to amplification, the short pulses need to be stretched to several hundred picoseconds long, to avoid damage to the optical components in the amplifier cavity. After the amplification has occurred, the pulses are re-compressed, so that the 100-fs output pulse is obtained. The near-IR (800-nm) pulse can be frequency-doubled to 400 nm, tripled to 266 nm, or converted to tunable visible light by use of an optical parametric amplifier (OPA), so that wavelengths suitable for photoexcitation work are generated.

In the foregoing segment an attempt has been made to provide a broad survey of light sources that have proven useful to the photochemical community for studies in the area of photoinduced electron transfer. The survey is by no means comprehensive; to do so would soon exhaust the page allotment. The coverage has, rather, been aimed at the more widely used devices, examples of which are extant in the authors' laboratory.

4.4 Detection and Measurement Techniques

In the above section the photodevices that can be employed to reach the appropriate reactant state were outlined. In the remainder of the chapter, the devices and instruments for monitoring the subsequent change and determining the rate characteristics will be discussed. By far the most frequently employed diagnostic techniques are optical absorption and emission spectrometry; other less-used methodologies include light-scattering spectrometry, and the electron-spin-based spectroscopies, such as EPR, ENDOR, and CIDNP. These last three are not addressed in this review.

4.4.1 Optical Absorption Spectrometry

Principles and limitations

In electron-transfer reactions, the movement of an electron from the reactant state to the product state generates new species that have different electronic configurations. Different electronic configurations in a molecule give rise to different

electronic absorption spectra, and therefore monitoring optical absorption changes during an electron-transfer reaction has proven to be a sensitive and widely used method of following the time course of a photoinduced reaction.

When a beam of light at some wavelength λ is incident on a sample containing an absorbing compound, the logarithm of the ratio of incident light intensity (I_0) to that of the transmitted light intensity (I) is termed the absorbance (A_λ) of the sample. A_λ is related to the molar concentration (c) of the absorbing species according to

$$A_\lambda = \log(I_0/I) = \varepsilon_\lambda c l \quad (11)$$

where ε_λ is the molar decadic extinction coefficient (units of $\text{mol dm}^{-3} \text{ cm}^{-1}$) at the wavelength λ , and l is the optical path length of the sample. Thus, A_λ is directly proportional to the concentration of the absorbing species and, when the species concentration changes with time, then $dA_\lambda/dt = dc/dt$. Hence, the time profile of the change in A_λ is directly related to the time profile of the absorber concentration. Equation 11 shows that $A_\lambda(t)$ is obtained by monitoring of the time dependence of the change in the transmitted light intensity, $I(t)$, at a constant value of I_0 . When the latter cannot be kept constant, its value must also be determined for every $I(t)$ value (see below). $I(t)$ is a light-fluence quantity, which is converted to electronic charge by a photosensitive detector. The ultimate measurement is of a voltage–time profile, $V(t)$, which is referenced to V_0 , derived from I_0 . Thus

$$A_\lambda(t) = \log[V_0/V(t)] = \varepsilon_\lambda c(t) l \quad (12)$$

From the time dependence of V , thence of A_λ , and eventually of c , the rate parameters being sought can be determined.

From the above it is apparent that A is a function of two variables, namely time and wavelength. The time dependence leads to dynamics information as outlined above; the wavelength dependence provides spectral information, useful for assignment or structural purposes. When values of $A(\lambda, t)$ are obtained for a photo-initiated sample, a dynamic surface (A – λ – t) can be constructed; this contains the totality of the information available from an optical absorption experiment.

Two distinct types of experiment have been employed to generate $A(\lambda, t)$ data for transient species. One is a continuous recording method in which a photodetector (photodiode, photomultiplier tube–PMT) monitors the transmittance of the sample at fixed wavelength (λ) in a continuous manner, before, during, and after the initiating light pulse. The detector output is fed to the input amplifier of a waveform-recording device such as a digital oscilloscope, which acquires the waveform and stores it for eventual processing. Thus, recording of the $V(t)$ profile is done in real time. Repeating the process over a series of wavelengths allows the investigator to build up the dynamic surface for the light-induced transient which is, in principle, capable of providing rate data at different wavelengths and time-dependent spectra. In what follows, this type of experiment will be referred to as the continuous photoelectric method. Examples of time-resolved spectra and kinetic profiles obtained in the authors' laboratory using the photoelectric method are shown in Figure 4 (see

later on). The photoelectric method is excellent for providing kinetic information, since the time profiles from a single experiment arrive at the digitizer as analog voltage waveforms that can be digitized into as many bits of information as required. This lends itself to highly precise determinations of rate parameters. The same is not true of the spectral information, which is taken point-by-point, and the number of points taken, and hence the precision of the obtained spectrum will to some extent depend on the investigator's patience.

The major limitation of photoelectric recording is what can be thought of as the nanosecond barrier. This limitation arises because of the intrinsic time response of the electronic devices that must be used to acquire and process the photon-generated cathode current of the PMT or photodiode. All such devices have impedance, and even the best-designed circuitry has stray capacitance of typically 20 pF which, when combined with the 50- Ω industry/standard of electronic amplifiers, yields a RC time constant of 1 ns. Hence, instruments that are built up from conventional electronic units will have minimum rise times in the ns region and therefore chemical changes that have lifetimes less than 5 ns, say, will be severely deformed. Of course, other reasons may intervene (e.g. 10-ns-wide laser pulses) that make the instrument response even poorer than implied by the nanosecond barrier.

It is important to find a way around the nanosecond barrier problem if reactions occurring in the subnanosecond regime are to be investigated, and the pump-probe method provides the path. Here, two light pulses are generated; one to excite the sample (prepare the reactant state) and one to probe the system at a given time post-excitation. In the early experiments, high-energy flashlamps were used for generating observable concentrations of short-lived species and lower energy flash sources were used as interrogating beams. The two flashes were electronically delayed, one with respect to the other. This procedure stems from the methodology employed by Norrish and Porter in 1949 as part of their invention of the technique of flash photolysis which led to their being awarded the Nobel Prize in Chemistry in 1967 and which revolutionized the study of short-lived transient species inasmuch as it proved capable of generating and analyzing chemical species with lifetimes shorter than a few milliseconds [15, 52]. (It is interesting to note that some 50 years after Norrish and Porter's 1949 *Nature* paper [15] that reported the development, Ahmed Zewail was awarded the 1999 Nobel Prize in Chemistry for using Norrish-Porter concepts on the femtosecond timescale to investigate the transition-state domain.)

In the modern era, flashlamps have been superseded by pulsed laser sources which are monochromatic, highly collimated, and have a much higher repetition rate. With a single laser source, the probe pulse can be a small part that is split off from the main pump beam, to therefore be of the same wavelength. Such an arrangement is restricted to the measurement of the kinetics of repopulation of ground-state absorption removed (bleached) by the pump pulse. This method has been employed fruitfully in several laboratories [53-56].

Significantly more information is available when the probe pulse is a white-light continuum and a spectrograph is used to disperse the spectral distribution of the beam transmitted by the sample. Under these conditions, one obtains an absorption spectrum of transient species formed, or ground-state species removed by the ini-

tiating pulse. This spectrum will be registered at a time that is given by the difference in arrival times at the sample of the pump and probe pulses, and it will be an average over the temporal width of the probe pulse. An alternative method of obtaining spectral information is to employ a probe beam of a selected, but changeable wavelength. Such a beam can be isolated from a continuum by one of a set of interference filters, or it can be generated by an optical parametric amplifier (see above) which can be scanned to provide spectral coverage [57, 58]. In both these instances the detector is a commonplace photodiode.

Repetition of the spectrum acquisition sequence at different probe-pulse arrival times provides a series of spectra delayed with respect to each other. Thus, time resolution of the reaction is achieved in a point-by-point manner, from which the intensity–time–wavelength surface can be produced.

In this experiment type, the detector of the transmitted probe light behaves as a photon integrator only and the time resolution derives from the instrument's capability for measuring the difference in the time of arrival of the pump and probe pulses. This capability provides an intrinsic limitation to the pump–probe method, which depends critically on the width of the pulses being employed. As indicated earlier, exceedingly short duration pulses are commonplace these days.

A more practical limitation to this method involves the regime of large time differences. When a single laser is used as the source of both pump and probe pulses, the time difference is generated by delay of the probe with respect to the pump with an optical delay line. Such devices are excellent for delays in the subnanosecond region and up to 3 ns or so, but their alignment and operation becomes very cumbersome for delay times in excess of 10 ns or so, and they are rarely used in this regime. Investigators have used a pair of individual light sources for the longer delays. Thus, Porter and his colleagues, in their original microsecond experiments, used a pair of flashlamps, one to pump and one to probe [15, 51].

More recently, others have employed two Q-switched lasers to generate delays in the long nanosecond region [59, 60], especially where spectra and not kinetic profiles are being sought. In the above development, nothing has been stated about the analytical wavelength region employed in photoelectric spectrometry or pump–probe spectrometry. In fact, most of the work carried out to date centers on the UV–visible wavelength region, although there is increasing activity among the research community in exploring the mid-infrared (fingerprint) region; there will be more about this latter subject later on.

Examples of instrumentation

In this section, two operational instruments based on the principles discussed in the previous sections are described. One is useful for monitoring processes with reaction times in the 10^{-8} s to $>10^0$ s range—a so-called suprananosecond kinetic spectrometer. The other—an ultrafast kinetic spectrometer—is employed for reactions occurring in the range $<10^{-12}$ s to $>10^{-9}$ s. Both these spectrometers are in use in these authors' laboratory for investigating photoinduced electron-transfer reactions, *inter alia*. The use of these homegrown instruments to illustrate this chapter is not

Figure 2. Schematic layout of a typical suprananosecond kinetic spectrometer: Q: Q-switched laser with harmonic generators; L: lens; X: cw monitoring lamp; S: shutter; A: aperture (see Figure 3 for detail); C: sample cuvette; M: monochromator; PM, PD: photodetectors; O: digital oscilloscope; PC: personal computer.

meant to indicate anything other than that these are typical of similar instruments found worldwide in the laboratories of the electron-transfer community.

Suprananosecond kinetic spectrometer

A suprananosecond kinetic spectrometer is schematically shown in Figure 2. The excitation source is a Q-switched Nd:YAG laser (Continuum Surelite I) which is capable of a 10-Hz repetition rate but is typically used in the “replicate-one-shot” mode. The nominal 6-ns pulse can contain up to 450 mJ at 1064 nm, which decreases after harmonic conversions to 532 nm, 355 nm, or 266 nm. In addition to these harmonic lines, the 355-nm line can be used to pump an OPO (Opotek Magicprism), which provides tunable radiation in the range 420 nm to ca. 900 nm. The selected photolysis beam is incident on one face of a 10 mm × 10 mm quartz cuvette containing the sample.

In experiments in fluid solutions where absorbance at the excitation wavelength (λ_{exc}) can be controlled, it is advantageous to arrange that the deposition of pho-

Figure 3. Detailed views of the geometrical relationships of the laser beam, the cuvette, and the monitoring beam.

tons, and thereby the production of excited states is as homogeneous as possible in the interrogated volume. The Beer–Lambert law ensures that the concentration of excited states will decline exponentially with distance from the laser input face. However, as stated below, the interrogation volume is restricted to the first mm from the laser input face and thus absorbance values at λ_{exc} of one per cm or even greater can provide close to homogeneous energy deposition.

The monitoring light source is either a 150-W xenon arc lamp [61–64] or a 100-W quartz–halogen lamp. The path of the monitoring light is at right angles to the excitation beam and it interrogates the first 1 mm of the irradiated volume behind the laser input face (see Figure 3). This is arranged by appropriate placement of lens and an aperture.

Xenon arc lamps operate at high pressure (20 atm) with a short arc configuration and require a highly stable DC power supply for low baseline ripple. The lamp output is a smooth continuum with weak superposition of lines in the visible and strong lines in the near-IR. Xenon arc lamps are prone to suffer from baseline ripple with a frequency less than ca. 1 kHz. This can be caused by power-supply fluctuations or by wandering of the arc. These ripples can cause severe distortions in the time profile of low-intensity transient absorptions on the millisecond or longer timescales. The current supply to the xenon lamp can be pulsed to high intensities [65–68] to increase the radiance. A 250-W xenon lamp with a 450-amp pulse has been reported to have a 700-times increase in radiance in the UV, 300-times increase in the visible and 50-times in the IR [65]. Tungsten and quartz–halogen

lamps [69–73] are less subject to ripple and provide much more stable outputs, albeit with much reduced intensities. Tungsten emits a continuum from the near-UV into the IR [74]. The quartz–halogen lamps have quartz filaments and are run at higher temperatures than tungsten lamps, namely at 3000 to 3200 K, which gives somewhat higher UV outputs. A quartz–halogen lamp can be used as a standard for calibrating the spectral response of spectrometers [75]. The high-wattage lamps are used with shutters, to protect the sample from undue photolysis, and the detector from unnecessary fatigue.

The lamp housing is equipped with a rear reflector and a fused-quartz, four-element, spherically corrected $f/0.7$ lens assembly (Oriel) to collect the light and transfer as much as possible through the 1-mm aperture in front of the cuvette. The exiting beam is re-collimated and focused onto the entrance slit of a 0.22-m monochromator (Spex 1681) which disperses the white light into its component wavelengths and isolates a narrow range of wavelengths at the exit slit. The grating may be either ruled [76–81] or holographic [80, 82–85]. Ruled gratings can contain periodic ruling errors that result in ghost images in the dispersion plane and holographic grating is therefore preferred. Holographic gratings are manufactured from photoresist materials that are exposed to interference fringes produced from diffracted monochromatic light. They are free of ghost images. There is a multitude of different types of monochromators with different configurations [76–78, 86, 87]. One important consideration is the f -number, defined as

$$f = f_c/d_c \quad (13)$$

where f_c is the focal length and d_c the diameter of the collimating mirror. The lower the f -number, the more light is transmitted by the device. When designing an optical system, it is important to arrange for the beam that is incident on the entrance slit of the monochromator to have a convergence that matches the f -number of the monochromator. If the f -number of the entrance optics is smaller than the f -number of the monochromator, then the grating will be overfilled and stray light may be increased. If the f -number of the entrance optics is larger than that of the monochromator, then the area of the grating that is illuminated is decreased, and the resolution of the instrument suffers [77, 80]. The grating in most frequent use is a holographic type and covers the range from 230–800 nm with a blaze at 400 nm.

The photodetector that monitors the intensity and time profile of the monochromatic light issuing from the exit slit of the monochromator is a side-on photomultiplier tube (Hamamatsu 928), which has an excellent response in the UV, visible, and near-IR to about 900 nm. Photomultiplier tubes (PMTs) are light-detection devices capable of measuring weak fluxes of light, as low as 10^{-15} W. They depend on the photoelectric effect for their function, in which electrons are emitted from the illuminated part of the active surface. It consists of a photosensitive cathode, an electron-multiplier section (dynodes), and an electron collector (anode), all sealed in a vacuum tube. When photons of the appropriate frequency are incident on the photocathode (held at a high negative potential), electrons are emitted and are directed onto the first of the dynode series where secondary emission of electrons occurs. Each dynode is held at a lower negative voltage than its predecessor so that

the arriving electrons possess about 100–200 V of energy and thus each arriving electron generates several secondary electrons, thereby producing a cascade that contributes to the multiplication process. In a typical 11-dynode stage photomultiplier tube, each stage provides an amplification of ca. 2.5, leading to an overall gain of 10^6 or so. The electrons leaving the final dynode are collected by the anode, and this charge, when run to ground through a load resistance, produces the output signal voltage. The photomultiplier tube employed in the current instrument uses just five stages of gain, with the sixth employed as the collector electrode. In this way, gain is sacrificed for improved time response [88]. Photodiode/fast amplifier combinations can replace photomultiplier tubes, and this is particularly advantageous in the near-IR where photomultiplier photocathodes tend to have poor quantum efficiencies [89]. It is important that the photodetector must respond linearly to the light intensity. This is checked by inserting neutral density filters between the lamp and the monochromator entrance slit and confirming that the detector output corresponds to that expected from the transmittance of the filter. Excellent descriptions of the comparisons between detectors and the spectral response characteristics of different photocathodes have been published [90–91].

The current waveform on the anode of the photodetector is fed to the input connector of a transient digitizer/digital oscilloscope where it is converted into digital format and read into a PC. The resulting stored data can be processed for spectral/dynamic content by one of several available commercially available data manipulation software packages.

The suprananosecond instrument described, in common with almost every other such instrument, is a single-beam spectrometer inasmuch as it records the absorbance difference between the pre-pulse and post-pulse values, that is, the combined spectra of the ground state and product state are involved. Only when the sample has zero absorbance prior to the excitation event, does the experiment provide absolute absorption spectra. An example of this is presented in Figure 4, which shows the transient difference spectrum of the triplet state of a metallophthalocyanine compound, measured point by point from absorbance–time profiles such as the one shown in the inset. The spectrum in Figure 4 has positive and negative values of difference absorbance. When the absorbance is negative, as shown at 680 nm, the ground state removed by the pulse has a higher ϵ value than the excited state generated concomitantly. When positive (530 nm), the excited state has a higher ϵ than that of the ground state. When both states absorb equally, there is a zero value in the absorbance difference spectrum.

In some laboratories [92, 93], the spectrometer outlined above has been modified to include an optical multichannel analyzer (OMA) for obtaining spectral information in a “single shot”. In this arrangement, the monitoring beam is steered into a spectrograph (“polychromator”) after the sample which disperses the white light over a diode array/CCD detector situated at its focal plane. Time resolution requires some kind of “gating” which can be provided by 1) an electromechanical shutter in the monitoring beam, 2) use of a pulsed lamp as the monitoring source, or 3) application of a gating pulse to an intensification stage on the detector. The detector thus provides a dispersed absorption spectrum of the species produced in the sample by photoexcitation, each pixel corresponding to a particular wavelength

Figure 4. *Main figure:* transient absorbance spectra recorded at three-times (5, 59, and 180 μs) post-355-nm excitation of a solution of bis(trihexylsiloxy) phthalocyaninato- Sn^{IV} in toluene solution. *Inset:* the time profile of the absorption decay at 520 nm.

interval. The recorded spectrum is an average over the temporal width of the monitoring beam pulse. Kinetic information can be obtained by the spectrum collection being repeated at a series of times between arrival of the excitation and the interrogating pulses. While the OMA technique will generate a dispersed absorption spectrum from a single excitation event, in practice, multiple repetitions are employed to improve the signal-to-noise response.

The preceding narrative has focused on the UV–visible spectral region for interrogating the transient states generated. However, in recent years, there has been increasing activity in mid-infrared detection of time-resolved spectra. The major advantage that IR spectrometry brings is that it offers the possibility of structural as well as kinetic information, and it provides distinct absorption bands for some species that have only indistinct UV–visible absorptions. The major drawback to IR observations is that extinction coefficients are generally much smaller than in the visible region; this places additional demands on instrumental sensitivity. Nevertheless, several interesting reports of suprananosecond studies have appeared [94–97].

Ultrafast kinetic spectrometer

A schematic layout of the system extant in the authors' laboratory is shown in Figure 5. The laser assembly is Ti–S based with a titanium–sapphire oscillator (SpectraPhysics, Tsunami) that is pumped by a frequency-doubled, diode-pumped

Figure 5. Schematic layout of an ultrafast pump-probe spectrometer. *Top left panel:* A: cw diode-pumped, frequency-doubled, Nd:YAG laser; B: mode-locked Ti-S oscillator; C: regenerative Ti-S amplifier; D: Q-switched, frequency-doubled Nd:YLF amplifier pump laser; E: second/third-harmonic generators or OPA. *Lower right panel:* F: continuum generation; G: sample; H: CCD spectrograph. The double arrow indicates the optical delay stage, and the dashed line indicates the pump-beam trajectory.

5-W cw Nd:YAG laser (SpectraPhysics, Millennia). The oscillator output (ca. 10 nJ, 70 fs, 80 MHz) at 800 ± 30 nm is steered into a Ti-S regenerative amplifier (Positive Light, Spitfire) which is pumped with a frequency-doubled (527 nm) Q-switched Nd:YLF laser (Positive Light, Merlin) operating at 1 kHz. Before entering the amplifier cavity, the 70-fs pulse is stretched to lower its peak power, then steered into the cavity where its amplitude is increased by ca. 10^5 . The amplified pulse is subsequently recompressed to ca. 100 fs. The output of the amplifier is typically 1 mJ per pulse at a repetition rate of 1 kHz. It can be wavelength-tuned over a range of 780 nm to 820 nm. For obtaining useful excitation wavelengths (400 nm, 266 nm), the output of the amplifier is coupled into a harmonic generator (CSX, SuperTripler). For achieving tunable excitation wavelengths in the visible and near-IR regions, the 800-nm beam is employed as pump for an optical parametric amplifier (OPA-800, SpectraPhysics).

A fraction of the amplifier output light (800 nm) is split from the main beam for continuum generation prior to harmonic generation. This is accomplished by the red light (a few tens of μ J) being focused into a 1-mm thick sapphire plate where, at

sufficiently high peak powers, nonlinear optical processes such as stimulated Raman and multiwave mixing occur within the beam waist. This process (self-phase modulation) results in the production of a coherent white-light beam along the pump-beam direction and having a similar time duration. Before continuum generation, the red-light beam traverses an optical delay line that provides an experimental time window of 1.6 ns with a step resolution of 6.6 fs. The energy of the probe pulses is ca. $5 \mu\text{J}/\text{cm}^2$ at the sample.

The pump beam is typically up to $50 \mu\text{J}$ per pulse, although with OPA output this is rarely possible. The spot size at the sample normally has a ca. 2-mm diameter, but again this varies with conditions. A mechanical chopper operating at 30 Hz is positioned in the pump beam upstream of the sample. This provides a series of pump on–pump off exposures (see below). The angle between pump and probe beam is kept as small as possible and is typically $5\text{--}7^\circ$. The liquid sample is held in a reservoir and is pumped through a flow cell (path length of 2 mm, or less). After traversing the sample, the probe beam is focused into a $400\text{-}\mu\text{m}$ fiber-optic cable and entered into a CCD spectrograph (Ocean Optics, SD1000) capable of 0.5 nm per pixel resolution over the range 400 nm to 800 nm. Spectral information is passed from the spectrograph to a PC where it is sorted according to whether it is a pump-on or pump-off sequence. The chopper sync-out signal is used by the software as an indicator of the state of the chopper. The pump-off signals provide the I_0 data, and the pump-on data provide the corresponding I values (Eq. 9). Typically, 4000 excitation pulses are averaged for the transient spectrum at a particular delay time to be generated. A PC with LabView (National Instruments) software acquires data from the CDD spectrograph and operates the delay line. Repetition of the sequence at a series of delay line settings allows the generation of a dynamic surface, and absorbance data at a particular wavelength as a function of delay time provides time profiles.

The instrument response function (10 % to 90 % of rise) of the ultrafast spectrometer is ca. 250 fs. Figure 6 shows an example of a dynamic surface and Figure 7 depicts a reaction–time profile obtained on the instrument described above. The system described is a typical example; similar spectrometers are found in laboratories around the world. There are variants, largely concerning the pump laser. For example the pump–probe technique has been used to great effect with dye-laser sources from which subpicosecond pulses are available [98–99]. Mode-locked Nd:YAG and Nd:glass lasers have similarly been employed. As described in an earlier section, pulse durations for these laser types are suprapicosecond, but they have proven very useful where reaction times are 50 ps and longer [100, 101]. As with the ultrafast systems, continua can be generated if, for example, residual near-IR light is used after the harmonic generation process and the detection system is based on diode-array spectrography [102–105]. In addition, there have been reports of streak cameras being employed as time-resolved detectors in experiments where continuum generation was avoided [106–108].

Ultrafast mid infrared detection

The majority of ultrafast instruments have employed electronic absorption spectrometry for determining the ultrafast dynamic properties of the systems of interest. However, in recent years some investigators have successfully turned their attention

Figure 6. A dynamic surface generated by absorption of 400-nm light pulses in an aqueous solution of tetrakis(sulfonatophenyl)porphinato Ni^{II} . The positive feature indicated by "A" is an immediately formed absorption with a peak at 490 nm. This decays with fast and slow components (see Figure 7). The negative feature indicated by "B" is loss of absorption at the wavelength of the ground state due to removal of some fraction of its population upon photoexcitation. This recovers only slightly over the 5-ps time window. The positive feature labeled "C" which decays only slightly over the 5-ps time window is possibly another part of the longer-lived contributor at 490 nm. Careful scrutiny of the surface shows that the fast component at "A" has a wavelength maximum at 490 nm, whereas the slower contributor has a maximum near 460 nm. Surfaces such as this contain a wealth of information on a single page.

to the mid-IR spectral region, to measure the vibrational properties of short-lived transient states, and, hence, deduce information about structural features. Pump-probe excitation sources employed have been either amplified dye lasers or Ti-S lasers; detector systems have been based on conventional mercury cadmium telluride (MDT) technology [108–115]. Recently, Okamoto has developed detection technology based on optically heterodyned absorption anisotropy [116–117]. This provides improved signal-to-noise ratio for spectral detection, but kinetic information is difficult to obtain.

4.4.2 Light-Scattering Spectrometry

In electronic absorption spectrometry, the spectral bands are broad and often featureless, thus providing minimal information as to the structure of the absorber.

Figure 7. A two-dimensional slice from the surface shown in Figure 6 at 490 nm, allowing rate-parameter evaluation. The fast component has a lifetime of some 860 fs; the slower component has a lifetime of 12.5 ps.

The use of the mid-infrared (fingerprint) spectral region is one way of improving the information content; another depends on light-scattering methods. Inelastic scattering between visible light and molecular systems leads to energy exchanges, and the scattered photons possess energies that are different from the incident ones by an amount equal to one or more vibrational quanta (the Raman effect). The scattered light can have lower frequencies (Stokes) than the incident frequency, or higher frequencies (anti-Stokes). Thus, the frequency of the scattered radiation reports on vibrational transitions in the scattering molecule and Raman spectrometry is therefore complimentary to mid-IR spectrometry. Raman scattering is very weak and only high concentrations of scatterer can be detected in this way. When the frequency of the incident light is close to that of an electronic transition in the scatterer, however, considerable enhancement of active Raman modes can be observed (resonance Raman effect). There is a growing number of investigators who have employed time-resolved resonance Raman (TR^3) spectrometry to study electron transfer and other characteristics of excited states.

TR^3 spectrometry

Lasers are the ideal interrogation sources for TR^3 spectrometry in that they have the narrow line width necessary for discrimination between Raman radiation and elastically scattered light; they also have the high intensities required to generate sufficient signal. Some investigators have used two pulsed laser sources; one to generate the transients and the other to obtain the TR^3 data. The experiment is

therefore of the pump–probe type. Nanosecond and picosecond pulses have been employed [118, 119]. The most frequently used detectors for TR³ have been photomultiplier tubes. Detailed descriptions of picosecond time-resolved Raman apparatus have been published [120–121].

Raman spectra are specific fingerprints for individual chemical species. Clear assignments can often be made if several species are present. The Stokes and anti-Stokes intensities are compared for the determination of the vibrational population ratios and vibrational energy flow on a time-resolved basis. Isotopic Raman spectra provide information on normal modes, geometry, and chemical bonding. Molecular distortions due to solvation changes can sometimes be observed in lineshape and position changes.

The usefulness of resonance Raman spectroscopy for investigating a photo-induced electron-transfer reaction can be exemplified by the well-known oxidative quenching of the MLCT excited state of Ru(bpy)₃²⁺ by MV²⁺. Additional support that the quenching of the excited state occurs by an electron-transfer reaction is given by a resonance Raman spectroscopy study [122]. When mixtures of Ru(bpy)₃²⁺ and MV²⁺ were excited and interrogated by two lasers, detailed vibrational spectra were obtained that could be matched with the Raman spectra of the redox intermediates, including the MV^{•+} ion. No evidence for an excited state of MV^{•+} was observed; this indicates that an energy-transfer process was not occurring.

Time-resolved Raman spectroscopy also provides valuable mechanistic information on quenching reactions of molecules such as trans-stilbene [123]. The fluorescence of trans-stilbene can be quenched by tertiary amines. TR³ spectra measured 60 ns after excitation contained peaks that could be assigned to the transient anion radical of trans-stilbene [123].

4.4.3 Fluorescence Instrumentation [124–126]

Introduction

In the electron-transfer process generalized in Eq. 1, one of the components of the reactant state may be fluorescent. This spin-allowed radiative process will thus be in competition with the nonradiative electron-transfer reaction and the two processes will contribute to the overall decay of the reactant state. The intrinsic lifetimes of fluorescent molecular states range typically from 10^{−11} to longer than 10^{−8} s. The occurrence of electron transfer involving the fluorescent state will shorten its lifetime and measurement of this quantity will therefore allow computation of the rate constant for electron transfer.

The kinetic scheme describing this situation can be written as follows:

$$\text{From this, } -d[A^*]/dt = -dI_{\text{f}}/dt = [A^*]_0 \exp(-t/\tau) \quad (16)$$

$$\text{and } \tau^{-1} = k_{\text{obs}} = k_{\text{f}} + k_{\text{et}} \quad (17)$$

Measurement of τ in the absence of the electron donor will therefore yield k_f , and in its presence, k_{obs} will be obtained, from which k_{et} can be evaluated. However, the proviso discussed earlier concerning product identity still applies, and the wise investigator will be concerned with whether it is electron transfer that is actually causing the quenching process. In the past twenty years, time-resolved measurements for fluorescence lifetime determination have become highly developed and they have been much used in electron-transfer research.

Sensitivity and specificity of fluorescence detection

Fluorescence detection is a very sensitive technique, capable of measuring concentrations as low as one part in 10^{10} . In comparison, absorption spectrophotometry is ca. 10^3 times less sensitive. The superior sensitivity of fluorescence is due to the fluorescence signals being measured relative to a zero background. The photomultiplier (or other detector) measures either photon arrival or the absence of photons. In absorption spectrophotometry, the signal is determined from the difference between two light intensity measurements, one the test and one the reference. As the concentration of absorber is reduced, the test and reference signals will approach each other in magnitude, and eventually the measurement of the small difference between two nearly equal large signals will become subject to large random error.

Instrumentation

Time-correlated single-photon counting [125–131]

Time-correlated single-photon counting (TCSP) has proven to be a much-used method for measuring fluorescence lifetimes. It is highly sensitive in that it requires only one photon to be incident on the detector per excitation cycle, and statistical analysis of the experimental data gives lifetimes with well-defined error limits. Commercial systems are available which allow lifetimes from 50 ps to many tens of nanoseconds to be measured with relative ease and high precision.

Figure 8 shows a typical schematic diagram of a TCSP system. The experimental setup requires an excitation source, sample chamber, a sensitive photomultiplier detector, and electronics that allow precise timing of the interval between the arrival of the pulse from the excitation source and the arrival of first fluorescence photon at the detector. In a typical experiment, a hydrogen-flashlamp excitation source produces low-intensity light pulses of a few nanoseconds' duration. Each pulse produces a fluorescence pulse, the fluorescence photons are emitted over a range of times after excitation with more photons being emitted earlier, and fewer emitted later as the excited state decays. Single-photon counting relies on the fact that highly sensitive photomultipliers are able to give measurable current output pulses after a single photon strikes the photocathode. This allows the delay time between the excitation pulse and the arrival of individual photons to be determined. The key to the precise timing is the time-to-amplitude converter (TAC). The TAC is a device that starts to charge a capacitor linearly upon command from the start pulse generated by a photodiode that senses the excitation pulse. It ceases to charge when commanded by the arrival of the fluorescence (stop) pulse. It subsequently outputs a

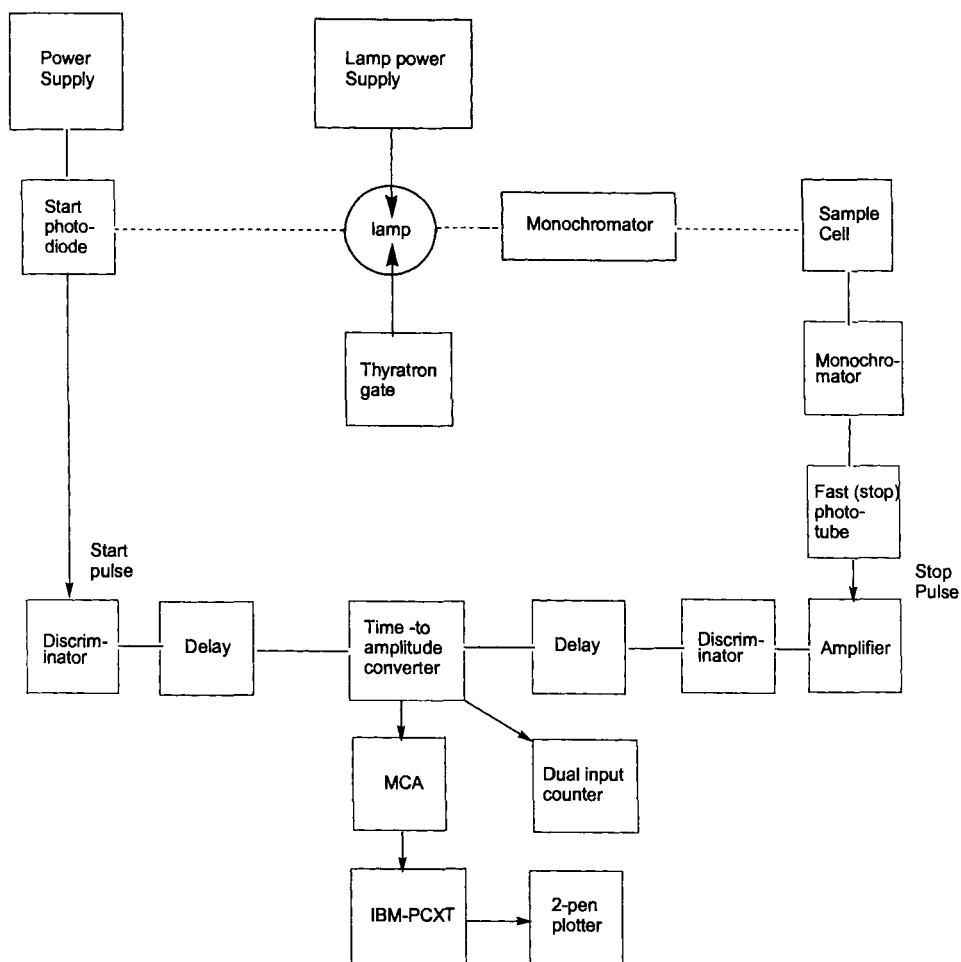

Figure 8. A schematic presentation of a time-correlated single-photon-counting instrument (see text).

voltage pulse whose amplitude is derived from the stored charge and is thus proportional to the time interval between start and stop pulses.

The voltage pulse produced by the TAC is fed to the multichannel analyzer (MCA), and is stored in a specific channel according to its amplitude, and hence time, post-excitation. The probability of a single photon event being counted is high soon after excitation and decreases with time. Repetitive operation of the TAC produces a probability histogram for the detection of fluorescence photons, which is identical to the fluorescence decay curve.

The fluorescence lifetime is obtained from this curve by an iterative curve-fitting program that deconvolutes the lifetime from the instrument-response profile (IRF). This describes the response of the instrument to scattered excitation pulses. A typical

Figure 9. The time profile for the decay of fluorescence from a solution of anthracene in degassed hexane. The data were obtained with a time-correlated single-photon-counting instrument such as that shown in Figure 8. The upper panel shows the raw data with a superimposed linear fit and the instrument-response function. The extracted lifetime was 5.14 ns. The lower panel shows the residuals. (Courtesy of Dr. F. N. Castellano).

scattering solution for obtaining an IRF is colloidal silica, or even a weak suspension of coffee creamer. The results of a typical experiment are shown in Figure 9. The plot consists of three traces, the instrument-response function, the raw experimental data and the numerical fit obtained from the fitting program. The data are usually displayed with a logarithmic ordinate in order to scale the intensity response that is usually arranged to cover over four decades and to clearly show any deviations between data and fit. The plot at the bottom of the diagram shows the percentage differences between the experimental curve and the calculated fitted curve, that is, the residuals. The deviations between the experimental data and the calculated best fits are often too small to be seen by eye, and an assessment of the best fit is normally carried out with statistical tests, such as point-by-point weighted residuals and autocorrelation functions. Full details of data analysis and evaluation can be found in the relevant literature [125, 126, 131].

Fluorescence upconversion [132]

Fluorescence upconversion (also called fluorescence sum frequency mixing) is a technique for measuring fluorescence lifetimes with time resolution in the subpico-second timescale. The upconversion method allows significant improvements in time resolution over the above-discussed time-correlated single-photon-counting (TCSPC) method. The latter has time resolution (with deconvolution) approaching 20 ps. Streak cameras do not allow for time resolution much below 1 ps. Barbara and coworkers described an upconversion instrument with a minimum 300-fs full-width-half-maximum (FWHM) response function [132]. Upconversion is an all-optical method of time-resolving fluorescence, analogous to an optical boxcar and akin to the pump-probe absorption method. It involves frequency mixing of non-coherent fluorescence from a sample with a coherent probe pulse. This is accomplished in a nonlinear crystal such as KDP or LiIO_3 . Time resolution is obtained by delay of the probe pulse relative to the excitation pulse, with use of an optical delay stage.

The apparatus can be divided into three main sections, laser-pulse production, amplification, and fluorescence upconversion. The ultrafast lasers employed for upconversion are those that have been described above. The experiment is a cross-correlation between the fluorescence pulse and the laser pulse. At time $t = 0$, the sample is excited by the ultrafast laser pulse. The resulting incoherent fluorescence (frequency $= \omega_f$) is collected and mixed in a nonlinear crystal (such as KDP) with the gating pulse (frequency $= \omega_l$) derived from the excitation source and arriving at time $t = \tau$. This frequency mixing of the fluorescence and probe beams generates light at the sum frequency, ω_{sum}

$$\omega_{\text{sum}} = \omega_l + \omega_f \quad (18)$$

The theory of sum-frequency conversion of incoherent light can be found in the literature [133–134]. The intensity of the sum-frequency light at a given delay time is proportional to the correlation function of the fluorescence intensity with the intensity of the ω_l beam. A time profile of the fluorescence intensity is obtained by change of the arrival time of one of the pulses with the aid of an optical delay line.

4.4.4 Frequency-Domain (Phase-Shift) Measurements [91, 135]

Over a substantial number of years the phase-shift or frequency-domain method has been employed for the measurement of fluorescence lifetimes. The technique requires the continuous excitation of a fluorescent sample with a source of varying intensity. The fluorescence response would normally be expected to increase and decrease to reflect the changes in excitation intensity. However, in a frequency-domain experiment the excitation beam is modulated at a high frequency, $\omega = 2\pi f$, to produce a sinusoidally changing intensity given by:

$$I_0(t) = A + B \cos(\omega t) \quad (19)$$

If the fluorescence from the sample has a lifetime much shorter than a half period, the fluorescence signal will vary in a sinusoidal manner, without phase shift. If the decay time is comparable with that half period, the sinusoidal signal from the sample emission is phase-shifted with respect to the excitation. For a single exponential lifetime τ , the fluorescence response from the sample is

$$I(t) = C\tau \left[A + \frac{B}{(1 + \omega^2\tau^2)^{1/2}} \cos(\omega t - \delta) \right] \quad (20)$$

The value τ can be obtained directly from the measurement of the phase angle, δ , between excitation and fluorescence.

$$\tan \delta = \omega\tau \quad (21)$$

The modulation ratio M is another valuable parameter that describes the modulation of the fluorescence intensity relative to the excitation intensity:

$$M = \cos \delta = \frac{1}{(1 + \omega^2\tau^2)^{1/2}} \quad (22)$$

Most commercial spectrometers contain a Debye–Sears cell [136], which employs a quartz crystal oscillating at a specified frequency to modulate the intensity of the excitation beam. A cross-correlation detection technique is generally used to measure phase angles at a frequency ω with the gain of the photomultiplier modulated at a frequency $\omega + \Delta\omega$, where $\Delta\omega$ is of the order of a few hertz. The detector signal contains a component at frequency $\Delta\omega$, which is filtered and used to obtain δ with high precision using digital signal-processing techniques. At a single modulation frequency, a single δ value is obtained and only single exponential lifetimes can be determined. However, if the excitation intensity is modulated at two different frequencies in consecutive experiments, the δ and M values should yield the same lifetime if the fluorescence decay is truly exponential. Alternatively, the two sets of δ and M values can be used to obtain τ_1 and τ_2 for the sample exhibiting bi-exponential decay. The laboratories of Lakowicz and Gratton have both been very active in developing frequency-domain fluorometry [91, 137–139].

An important development in the phase-shift technique is the use of a radio-frequency synthesizer as the driver for the Pockels cell modulator. In this way, the excitation beam can be modulated at any frequency between 1 and 200 MHz [137–139]. This approach allows use of cw lasers such as the He–Cd laser and even mode-locked lasers [139] as the excitation source. If δ and M are measured at six to ten suitably spaced frequencies, least-squares curve-fitting techniques can be employed to obtain lifetimes with greatly enhanced precision. Typical data obtained by this multifrequency technique make measurement of decay times as short as 10 ps possible. Gratton and coworkers have developed other curve-fitting procedures to analyze data obtained on a multifrequency phase-shift fluorimeter. These experiments include the construction of time-resolved spectra [140], measurements of ro-

tational relaxation times from fluorescence anisotropy data [141], multi-exponential analyses [142–143], and determination of distributions of lifetimes as continuous functions [143–144]; these greatly increase the power of the phase-shift technique.

4.5 Concluding Remarks

In this chapter an attempt has been made to provide an outline of how photo-excitation methods are useful for the student of the kinetic properties of electron-transfer reactions. The emphasis has been on the practice itself, the why and the how. The authors of other chapters of this series of volumes will discuss the manifold results of such studies and put them into the context of the current theories. There is no doubt that photoinitiation of electron-transfer reactions is a powerful technique that is in widespread use. One significant reason for its popularity must be that photoinitiation allows access to timescales on which the fastest of reactions occur. For example, Xu et al. reported recently [145] that the photoinduced electron-transfer reaction between rhodamine 6G and dimethylaniline (DMA) occurs in neat DMA with a lifetime of 85 fs. Reaction lifetimes shorter than this will surely be few and far between.

Acknowledgments

We wish to express our thanks to Ms. Anna Paola Pelliccioli and Mr. Alexei V. Gusev for providing the data from which Figures 4, 6, and 7 were generated, and to Dr. F. N. Castellano for providing Figure 9 and for insightful discussions about fluorescence lifetime measurements. Experimental facilities in these laboratories have been constructed with support from the National Science Foundation, the National Institutes of Health, and the Center for Photochemical Sciences at Bowling Green State University.

1 Reactivity Patterns of Radical Ions—A Unifying Picture of Radical-anion and Radical-cation Transformations

Michael Schmittle and Manas K. Ghorai

1.1 Introduction

The chemistry of charged radicals, both radical anions and radical cations [1], has attracted much attention over the last two decades [2]. Despite a growing number of electron-transfer (ET)-promoted reactions that proceed with high selectivity and with unprecedented low activation barriers, however, most preparative chemists are still hesitant to use ET concepts when mapping out strategies for interesting synthetic target molecules. The reluctance to use radical-ion chemistry is firmly founded in the common notion that ET-initiated processes are mostly extremely complex transformations involving short-lived radical-ion intermediates the reactivity of which is hard to control and to predict. In our analysis covering several hundred transformations of odd-electron charged species [1], however, the majority of reactivity patterns proves to be extremely similar, irrespective of whether radical anions or radical cations are involved, making predictions on the *primary reaction channel* very reliable. Because a large body of kinetic data has recently become available on the reactivity of radical ions, it is now possible to map out the primary reaction channels not only conceptually but also on the basis of reliable data. We hope that the following unifying treatment, although it might not do justice to every possible individual case study in the literature, provides a helpful guide to the understanding of the fascinating chances of radical-ion transformations.

1.2 A Unifying Picture of Radical-anion and Radical-cation Chemistry

Radical ions are usually generated by one-electron reduction or oxidation processes starting from neutral compounds—an electron is either injected into the LUMO or removed from the HOMO. Even a simple MO picture of this process (Scheme 1)

Scheme 1. One-electron-transfer reduction and oxidation of RH.

suggests that the two radical-ion intermediates should share, at least qualitatively, some common features that will determine their chemical fate:

- 1) Both species carry an unpaired electron and a charge: hence, they will behave as either nucleophiles (or electrophiles) and likewise as radicals [3].
- 2) By electron injection into an antibonding orbital or electron removal from a bonding orbital characteristic bonds are weakened: as a consequence a plethora of bond cleavage processes is typical for both radical anions and cations.

To comprehend our categorization and to conceive the similarity between radical-anion and radical-cation reactivity the concept of the electrophore is of paramount importance. In simple terms, the electrophore is the ET active part of the molecule which either accepts or ejects an electron. To illustrate this concept it is helpful to analyze the reaction behavior of complex molecules after one-electron-transfer activation.

The alkaloid **1** [4] (Scheme 2), for example, has four donor functionalities (a)–(d) that could potentially be involved in the one-electron oxidation. At what site do we expect the oxidation to occur? For rapid analysis we approximate the various sub-units (a)–(d) by small, structurally related molecules the potentials of which are known. Accordingly, triethylamine and methyl acetate can serve as models for (c) and (d). As donors (a) and (b) are linked by conjugation, we treat them together and, indeed, find with *N*-acetylindoline a good approximation.

From the oxidation potentials provided above we have to conclude that oxidation will originate from the donor site (c) with the lowest E_{ox} , which is indeed observed in the selective photoinduced electron-transfer (PET) cyanation of **1** using DAP^{2+} (*N,N'*-dimethyl-2,7-diazapyreniumbistetrafluoroborate) as sensitizer [4].

As reversible redox potentials in solution are not available *in extenso* they can be replaced to a first approximation by ionization energies [5] or electron affinities [5, 6] either from experimental compilations or quantum-chemical calculations [7].

Scheme 2. Finding the relevant donor in alkaloid **1** containing several alternative electrophoric sites and the selective transformation of **1** [4] using PET.

Hence, a quick analysis might use LUMO energies from semi-empirical calculations for the analysis of the reduction of **3** (Scheme 3). Because the LUMO energy of acetone as model for site (a) in **3** is the lowest within the three electrophores, one must expect that an electron will be accepted at this site. This is indeed demonstrated in the PET reduction of **3** to a ketyl radical anionic intermediate using triethylamine as sensitizer [8].

While identification of the relevant electrophores in both examples above has enabled specification of the site at which the reaction will occur, it will be difficult for the non-expert reader to predict the primary reaction of the radical ion. Hence, we have written this review with the intention of providing *guidelines for the identification of primary reaction channels of radical ions and information about their kinetic reactivity*, which should enable the reader to set up defined ET-induced reactions even in polyfunctional molecules.

1.3 A Construction Set of Electrophores and its Relevance for Devising Selective Reactions *via* Radical Ions

The examples in Schemes 2 and 3 have illustrated the significance of identifying the electrophore with the lowest LUMO (or highest HOMO) energy for one-electron

Scheme 3. LUMO energies calculated using AM1 [9a,c] and the selective transformation of **3** [4].

reduction (or oxidation) reactions. But that is not sufficient! In addition, it is necessary to categorize the relevant electrophore according to its main constituents, i.e. to check whether it has mainly σ^* or π^* (for reductions) or σ , π or n character (for oxidations). This categorization is helpful because it will enable us to make predictions on the follow-up reactions of the radical ions.

If one wishes to induce a bond-cleavage reaction at the stage of the radical ion, one must choose either an acceptor whose LUMO contains a significant σ^ component or a donor whose HOMO has high σ participation.* In both, electron transfer will lead to a significant bond weakening, resulting in bond cleavage (Scheme 4).

If we like to induce bond formation at the stage of the radical ion, it is advisable to select either an acceptor whose LUMO contains significant π^ character or a donor whose HOMO has a predominant π (or n) component.* Electron transfer in both will lead to either radical or ion-type bond-formation reactions (Scheme 5).

The above considerations have emphasized the need to establish the main character of the LUMO (of acceptors) and likewise of the HOMO (of donors). For that

Scheme 4. Illustration of bond weakening in both σ^* radical anions and σ radical cations.

Bond formation through

Scheme 5. Illustration of the similar reactivity patterns of radical anions and radical cations in bond-formation reactions.

Scheme 6. Electrophores are often assembled from individual functional groups and bonds at the periphery.

purpose, the electrophore of interest should be analyzed with regard to the functional group(s) (halide, phenyl, carbonyl, amino etc.) and the peripheral bonds (such as C–C, C–H, C–Hal bonds) that have orbital overlap with the main functional group(s). It is indisputable that the acceptor (or donor) qualities of different groups and bonds will be different and that only those with the lowest individual LUMO (or highest individual HOMO) energies will be main contributors to the LUMO (or HOMO) of the electrophore (Scheme 6).

The main character of a composed electrophore will be determined by the character of the strongest contributor (acceptor or donor). Hence in the following, the acceptor properties of several common bonds and functional groups that are relevant for organic ET synthesis will be listed. Because of the lack of extensive electron affinity data, we have preferred to approximate the acceptor qualities by the LUMO energies as calculated by AM1 (Table 1) [9a, c, 10]. The calculations also enable categorization of acceptors as either σ^* or π^* .

Likewise, we have established a qualitative order of the donor properties of several bonds and functional groups. The ordering was based on ionization potentials [5], because these are readily accessible for many molecules (Table 2).

It is obvious that a reduction of a pure σ^* acceptor will lead to rather efficient bond weakening as much as oxidation of a σ donor will entail bond cleavage (Scheme 4). The numbers [11, 12] in Table 3 underline the drastic effect of one-electron transfer on the bond strength of appropriate σ^* acceptors and σ donors. In all cases the bond-dissociation energies (BDE) of the radical ions are much lower than those of the neutral precursors (Table 3).

As mentioned above, however, most acceptors (or donors) will not be pure σ^*

Table 1. Acceptor qualities (LUMO energies) of a variety of σ^* and π^* acceptors as determined by AM1 semi-empirical calculations [9a, c, 10].

Energy of LUMO	σ^* Acceptor (energy of LUMO, eV)	π^* Acceptor (energy of LUMO, eV)
+5 to +3 eV	C-H ethane (+4.1) C-F fluoromethane (+3.8) C-N dimethylamine (+3.5) C-O oxirane (+3.4) ^a C-O dimethyl ether (+3.2)	
+3 to +2 eV	C-C oxirane (+2.7)	C \equiv C ethyne (+2.1)
+2 to +1 eV	C-Cl chloromethane (+1.6) C-F tetrafluoromethane (+1.2)	C \equiv N acetonitrile (+1.7) C=C ethylene (+1.4) C=N acetonimine (+1.2) C=O methyl acetate (+1.1)
+1 to 0 eV	C-S dimethylsulfide (+0.9) C-Br bromomethane (+0.9) C-I iodomethane (+0.5)	C=O acetaldehyde (+0.8) Ph benzene (+0.6) C=N azirine (+0.6) Ar pyridine (+0.1)
0 to -1 eV	C-Se dimethylselenide (-0.5) ^b C-O C-S methyl mesylate (-0.7)	NO ₂ nitromethane (-0.1) Ar pyrimidine (-0.2) Ar phenanthroline (-0.7) Ar anthracene (-0.8)
-1 to -3 eV	S-S dimethyl disulfide (-1.5) C-Br tetrabromomethane (-2.1) C-O, C-S methyl triflate (-2.4)	Ar nitrobenzene (-1.1)

^aHigher-lying unoccupied MO.^bValue calculated by use of PM3 [9b].

acceptors (or σ donors). The relevant frontier orbital will be composed of two or more constituents, e.g. for benzyl halides and benzylsilanes (Scheme 7).

($\sigma^*+\pi^*$) radical anion (benzyl halide)

($\sigma+\pi$) radical cation (benzylsilane)

**Scheme 7.** The relevant frontier MO for benzyl halides and benzylsilane.

Let us examine the reduction of a benzyl halide, which is, according to our understanding a typical ($\sigma^* + \pi^*$) acceptor. ($\sigma^* + \pi^*$) radical anions are composed of σ^* and π^* components in the singly occupied orbital. If there is good overlap between them (stereoelectronic effect) then for a given C–X bond the weakening will be stronger the closer the energy of the σ^* and the π^* electrophore (cf. Scheme 8).

For the simplest case, i.e. compounds with the same kind of scissile bond (similar homolytic bond-dissociation energies and σ^* energies!), the splitting $E_{(\sigma^*-\pi^*)}$ provides a good measure of the bond weakening. Along this line, substituted benzyl bromide radical anions have a lower ΔG_{BDE} when the energy of the π^* LUMO is raised, because the σ^* character in the SOMO is increased [13].

Scheme 8. In a radical anion with a constant $\sigma^*(\text{C-X})$ energy $E_{(\sigma^*-\pi^*)}$ becomes larger when the energy of the π^* orbital is reduced. Hence, the σ^* character of the SOMO decreases.

A particular situation is met when the observed bond cleavage in the radical anion is not expected because of the low σ^* character of the SOMO, as observed in the reduction of aryl halides. For example, the analysis of 4-chloronitrobenzene based on AM1 [9a, c] calculations clearly indicates that the LUMO and the nLUMO do not share any $\sigma^*(\text{C-Cl})$ character. Actually, the lowest unoccupied orbital with a

sizeable $\sigma^*(C-Cl)$ component is the LUMO+3 orbital (Figure 1). Nevertheless, C-Cl bond cleavage can be initiated by first forming an aromatic π^* radical anion that undergoes activation by intramolecular ET to the LUMO+3 orbital (Scheme 9).

Conceptually seen, such an ET reaction is possible through the avoided crossing of both electronic states separated by the energy gap $\Delta E_{\sigma^*,\pi^*}$. In a more pictorial description, the π^* acceptor system serves as an intramolecular redox relay which helps to shuttle the electron to the $\sigma^*(C-Cl)$ orbital which is not accessible by direct

Scheme 9. 'Intramolecular ET' activates 4-chloronitrobenzene radical anion for bond cleavage.

reduction because of its higher energy. It is obvious that the π^* radical anion will undergo bond cleavage only in the presence of a low-lying $\sigma^*(\text{C-X})$; otherwise it will undergo typical π^* reactions, such as transformations with either electrophiles or radical species.

What we have summed up for radical anions is likewise valid for radical cations, except that they might contain, in addition to the σ and π donor sites, also n donor character. Hence, σ , $(\sigma + \pi)$, and $(\sigma + n)$ radical cations may undergo bond cleav-

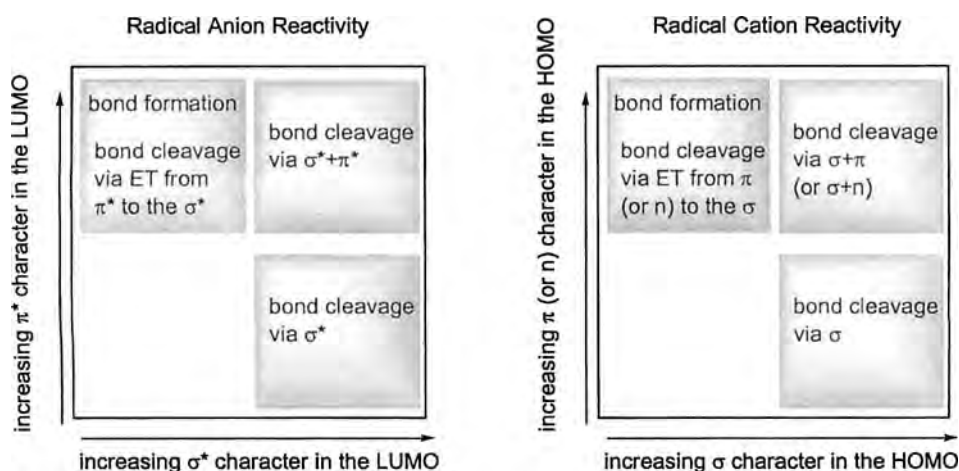

Figure 2. Radical anion and radical cation reactivity related to the character of the frontier MO of the redox-active molecule.

age because an electron is completely or partly removed from a bonding σ type orbital. In contrast, pure π and n radical cations, will undergo bond-formation reactions. Hence, to sum up the following picture of radical-ion chemistry may be sketched (Figure 2).

The above categorization emphasizes the similarities of the reactivity patterns of radical anions and radical cations. On the basis of the bond and fragment electron affinities (Table 1) or ionization potentials (Table 2), we can now devise systems that should undergo, for example, facile bond cleavage. As a prerequisite the σ^* (or σ) orbital representing the scissile bond has to be made a major contributor to the LUMO (or HOMO).

For example, C–Cl bonds can be easily cleaved by reduction because of their low-lying σ^* orbitals, whereas C–N bonds are much more difficult to cleave. Hence, it is advisable to incorporate the $\sigma^*(\text{C–N})$ into a $(\sigma^* + \pi^*)$ system by overlap of $\sigma^*(\text{C–N})$ with a low-lying π^* (e.g. from nitrobenzene). If overlap of the σ^* with a π^* is not possible, we still can set up a low-lying π^* redox relay to shuffle the electron to the σ^* by intramolecular ET.

The analogous situation can be arranged for bond cleavage in radical cations by using appropriately placed π or n donors to assist bond cleavage (Scheme 10).

To reveal the analogies in the primary reaction behavior of radical ions, we will use in this review the following structure:

- reductive and oxidative **bond-cleavage reactions**,
- reductive and oxidative **bond-formation reactions**, and
- ‘**pericyclic**’ **processes** under reducing and oxidizing conditions.

The vast body of examples covering many decades can obviously not be presented in a comprehensive manner here. Thus, we have decided to focus on a few selected examples from the recent literature; this should give the interesting reader the chance to find analogous examples through cited references. We regret that this way of presenting the material will not do justice to the numerous pioneers of radical-ion chemistry, whose work is extensively quoted in older reviews [14] or monographs [2]. The synthetic examples will be accompanied by kinetic and thermodynamic data to provide a qualitative and quantitative picture of radical-ion reactivity. When devising new synthetic schemes using these odd-electron species the combination of synthetic, kinetic, and thermodynamic aspects hopefully will serve as guide to the achievement of highly selective transformations.

1.4 Reductive and Oxidative Bond-cleavage Reactions

1.4.1 General Principles of Bond Cleavage

As discussed above, bond cleavage in radical ions is a result of the weakening of a single bond after electron transfer.

Bond cleavage

via σ^* acceptors / σ donors

via $(\sigma^* + \pi^*)$ acceptors / $(\sigma + \pi)$ or $(\sigma + n)$ donors

via π^* acceptors / π or n donors as redox relays

Scheme 10. Schematic view of bond cleavage in radical ions.

There are three distinct cases to be recognized depending on the σ^* (or σ) character of the LUMO (or HOMO).

- 1) If we deal with a pure σ^* LUMO (or σ HOMO), electron injection (or removal) will entail the strongest bond weakening effect. ET activation of such systems will always lead to bond dissociation.
- 2) In contrast, radical ions, whose LUMO has $(\pi^* + \sigma^*)$ character (or whose HOMO has $(\pi + \sigma)$ or $(n + \sigma)$ character), will experience reduced bond weakening after ET. Nevertheless, these systems still undergo efficient bond cleavage.
- 3) Molecules with pure π^* LUMO (π or n HOMO) character might undergo—in competition to other reactions—efficient bond cleavage, if they contain σ^* (or σ) orbitals which are energetically accessible by intramolecular ET.

Table 4. Acceptor type classification of aryl halides according to PM3 [9b, d] calculations.

Molecule	LUMO (energy)	Energy of lowest σ^* orbital
Fluorobenzene	π^* (+0.03 eV)	+2.33 eV (LUMO + 2)
Chlorobenzene	π^* (+0.06 eV)	+1.46 eV (LUMO + 2)
Bromobenzene	σ^* (−0.05 eV)	
Iodobenzene	σ^* (−0.43 eV)	
1,4-Dibromobenzene	σ^* (−0.32 eV)	
<i>p</i> -Cyanobromobenzene	π^* (−0.86 eV)	−0.45 eV (C–Br) +1.69 eV (C–CN)
<i>p</i> -Nitrobromobenzene	π^* (−1.39 eV)	−0.72 eV (C–Br) +1.10 eV (C–NO ₂)

To realize how the acceptor character can change from a σ^* to π^* system within a seemingly analogous series of compounds it is instructive to check the classification in Table 4.

While the cartoon-like depiction of the acceptor (or donor) in Scheme 10 emphasizes the analogies in radical-ion chemistry in a rather general manner, our compilation (Scheme 11) aims at providing more insight into some relevant functionalities involved in dissociation processes.

Irrespective of the electrophoric system involved in one-electron transfer-initiated bond dissociation one can easily derive the thermodynamic driving force for a such process by use of thermochemical cycle calculations [15]. Such estimates are particularly valuable as experimental numbers, because bond-dissociation data are scarce.

The cleavage of radical ions can proceed homolytically (or heterolytically) depending on whether the scission leaves (or does not leave) the charge mainly in the same region as in the radical ion. Change-over from homolytic to heterolytic bond cleavage can even occur in the same family of compounds, and the kinetic changes seem to be simply related to the thermodynamics of the bond cleavage and *not* to the mode of scission [16].

The kinetics of bond cleavage will be treated separately below according to the type of electrophore. Such data are important as cleavage rate constants can vary by more than ten orders of magnitude, depending on the nature of R and X in $\text{RX}^{\bullet-}$ [17].

The huge amount of bond-dissociation [18] examples makes this reactivity pattern one of the most prominent in radical-ion chemistry. We will therefore discuss this mode of reaction by providing thermodynamic and kinetic data along with some representative synthetic examples.

We encounter reductive bond cleavage of σ^* acceptors when there are no readily reducible π^* acceptors, such as aryl, carbonyl, and analogous functionalities present. Hence, this reaction pattern is commonly realized in aliphatic systems containing the electrophores depicted in Scheme 12, such as in simple reductions $R-Hal \rightarrow R-H$ [19]. Equally of importance is the dehalogenation of geminal [20] and vicinal dihaloalkanes [21], which has also been described for SO_2R , SR , OAc , OMe , OH ,

Common σ^* acceptors for reductive bond cleavage

C-Hal, C-O, C-S, C-Se, O-O, Si-Hal

Scheme 12. Frequently used σ^* acceptors that undergo rapid bond cleavage after reduction.

Scheme 13. 5-*exo-dig* cyclization initiated after reductive C–I bond cleavage [25].

and other leaving groups [21]. C–Hal bond cleavage is, moreover, frequently applied in $\text{S}_{\text{RN}}1$ reactions [2b] with aliphatic halides [22], in the generation of alkyl lithium compounds [23], and in cyclization reactions (Scheme 13) [24, 25].

C–O bond cleavage is most efficiently set up in strained systems, e.g. in oxiranes [26] and oxetanes [27], whereas O–O bond cleavage in cyclic peroxides [28] and C–S [29] and C–Se [30] bond rupture occur efficiently even in unstrained compounds. Si(Ge)–Hal bond cleavage [31] has become a valuable reaction, e.g. in the preparation of network polysilanes and polygermanes [32].

Kinetic and thermodynamic aspects

Pure σ^* acceptors, e.g. aliphatic halides and peroxides, are mostly believed to undergo dissociative ET, i.e. concomitant with ET into the σ^* orbital the bond elongates until it cleaves. Hence, over years it was believed that in such processes radical anions are generally not involved as distinct intermediates, although in very few examples parent anions had been observed, e.g. for CF_3Cl , CF_3Br , CCl_4 and CBr_4 [33]. Moreover, recent femtosecond studies revealed for the $\text{Et}_2\text{S}-\text{I}_2$ system after photoinduced charge transfer that reversible ET occurs in less than 150 fs (fastest trajectory) and is followed by the rupture of the I–I bond with the release of the first I atom in 510 fs [34]. Although semi-empirical calculations found both dissociative and non-dissociative ET with polyhalogen methanes [35], one must also take into consideration that the surrounding solvent will be important. Indeed, electron-transfer reduction of CCl_4 in the gas phase is predicted to yield an intermediate radical anion [36], whereas it is dissociative in $\text{H}_2\text{O}-\text{CH}_3\text{CN}$ (36:64 % *v/v*) [35]. As a consequence, the question of dissociative or non-dissociative ET has to be answered depending on the individual molecule and the reaction conditions.

For dissociative ET reactions thermodynamic bond dissociation data are not very meaningful, because they are intrinsically interwoven with the ET step. Nevertheless, some data are available, e.g. on halomethanes [37], and polyhalomethanes [11, 38].

Seminal work by Savéant and his group [39] has contributed to our understanding of the dynamics of dissociative ET, compared with the corresponding stepwise process [40]. Obviously, bond-dissociation energy, rather than bond dissociation free energy, represents the important contribution to the intrinsic barrier [41]. One must, moreover, take into account that dissociative ET can occur in the adiabatic (e.g. *tert*-butyl bromide) and in the non-adiabatic regime (di-*tert*-butyl peroxide)

[42]. Reorganization energies of such processes have been calculated and evaluated [43].

Irrespective of the mechanistic pathway, radical anions from σ^* acceptors undergo very rapid bond cleavage, a process that might be related to the toxicity [44] and carcinogenic activity [45] of polyhalogen alkanes, and which is of huge importance in synthetic chemistry.

Bond cleavage after reduction of ($\sigma^* + \pi^*$) acceptors

Synthetic aspects

Reductive bond cleavage in ($\sigma^* + \pi^*$) radical anions can be accomplished under milder conditions than with σ^* acceptors, because the π^* component can be used to move the reduction potential towards less cathodic potentials. The most common examples involve C–Hal bond cleavage in (hetero)benzylic and (hetero)allylic positions. Even those bonds can, however, be cleaved whose σ^* orbital is very high in energy, e.g. C–O, C–N, and C–C bonds (Scheme 14).

Common ($\sigma^* + \pi^*$) acceptors for reductive bond cleavage.

Combine

good σ^* acceptors : C–Hal, C–O, C–S,
C–Se, O–O, Si–Hal

with

good π^* acceptors

or poor σ^* acceptors: C–C, C–N

and allow for good overlap of the σ^* and π^* orbitals such as in

Scheme 14. Frequently used ($\sigma^* + \pi^*$) acceptors that undergo rapid reductive bond cleavage.

C–Hal bond cleavage is a main motif in simple reductions $\text{R–Hal} \rightarrow \text{R–H}$ [46] or for $\text{R–Hal} \rightarrow \text{R–E}$ by trapping the resulting anions with electrophiles E^+ [47]. Likewise, $\text{S}_{\text{RN}}1$ reactions [2b] involving benzyl halides [48], heteroarene methyl halides [49], and difluoromethyl quinones are frequently used [50]. Whereas bond cleavage of pure σ^* (C–N, C–O, C–C) acceptors is rather difficult, C–N [51], C–O [52], C–S [53], and C–Se bond rupture [30] can be readily realized in the corresponding ($\sigma^* + \pi^*$) systems. Even C–C bond cleavage is possible, for example in α -cyclopropylketones [54], but is restricted to a few instances. Other types of bond cleavage include rupture of the disulfide bond [55] and Se–S [56], Se–Se [56], and O–Si bond scission [52].

Scheme 15. Regioselective C–O bond cleavage as a key step in the synthesis of ptaquilosin [57].

Kinetic and thermodynamic aspects

($\sigma^* + \pi^*$) acceptors are often involved in thermal $S_{RN}1$ reactions [2b], because dissociative ET, for example between 4-nitrocumylchloride ($E^\circ_{SCE} = -1.12$ V) and 2-nitropropanate ($E^\circ_{SCE} = 0.077$ V), overcomes the sluggishness of an outer-sphere ET followed by bond dissociation (kinetic amplification through the $S_{RN}1$ process) [58].

C–Hal bond cleavage

When σ^*, π^* overlap in the radical anion is comparable within a series of compounds then thermodynamic factors will govern the kinetics. Following the trend in $\Delta G_{het}(RX^{\bullet-})$, bond cleavage in benzyl chloride $^{\bullet-}$ is dissociative, whereas the corresponding *p*-nitrobenzyl chloride $^{\bullet-}$ undergoes bond scission at 4×10^6 s $^{-1}$ [59]. The situation becomes somewhat more complicated when we compare the C–X bond cleavage of different groups X, because then the different homolytic bond-dissociation energies and σ^* energies also become important. For example, bond scission in benzyl halide $^{\bullet-}$ usually follows the order $BzBr^{\bullet-} > BzCl^{\bullet-} > BzF^{\bullet-}$ [60, 61]. Bond weakening is also responsible for the complete defluorination of trifluoromethylarenes— $NC-C_6H_4-CH_2F^{\bullet-}$ ($k = 7 \times 10^6$ s $^{-1}$) cleaves more rapidly than $NC-C_6H_4-CHF_2^{\bullet-}$ ($k = 4 \times 10^5$ s $^{-1}$) and $NC-C_6H_4-CF_3^{\bullet-}$ ($k = 3.8 \times 10^1$ s $^{-1}$) [62].

C–O bond cleavage

After one-electron reduction of cyanoanisoles the C–O bond rupture is very slow [63]. Much more rapid and in line with the driving force $\Delta G_{het}(RX^{\bullet-})$ is bond cleavage in $ArCOCH_2-OPh^{\bullet-}$: $Ar = pMeOPh$ at $k = 1.2 \times 10^7$ s $^{-1}$ compared with $Ar = Ph$ at $k = 7.0 \times 10^5$ s $^{-1}$ and $Ar = pCF_3Ph$ at $k = 1.0 \times 10^3$ s $^{-1}$ [64]. The role of the anionic leaving group Y has also been investigated in the bond scission of α -phenoxyacetophenones $PhCOCH_2OPh-Y$ [65]. Here, the rate constant correlates well with σ ($\rho = 3.1$) [66], because of the thermodynamic contribution to the activation barrier, as required by the Savéant model [17, 40, 67]. In this model the cleavage is viewed as an intramolecular dissociative ET, in which the electron is transferred from a π^* to the σ^* orbital of the bond to be cleaved.

C–X bond cleavage

It has been demonstrated that in ($\sigma^* + \pi^*$) acceptors even bonds (e.g. C–C) with very high-lying σ^* orbitals, which are neither accessible in σ^* acceptors by direct

electron injection nor in π^* acceptors by intramolecular ET, can be broken. To effect such difficult processes, the ($\sigma^* + \pi^*$) acceptor must have a weak homolytic bond and a high reduction potential, and the anion produced should be very stable [68]. By following these rules, rate constants of C–C bond cleavage in 1,2-diarylethane $^{\bullet-}$ were increased from 8×10^5 to $>3 \times 10^{10} \text{ s}^{-1}$; this enabled the design of interesting self-destructive electron acceptors [68]. Analogous C–S bond scission is feasible, but much slower [69, 70].

Bond cleavage after intramolecular ET via π^* redox relays

Many compounds undergo reductive C–X bond cleavage even though the LUMO does not have observable $\sigma^*(\text{C–X})$ character; examples are aromatic and vinylic halides [72] where the C–Hal bond is located orthogonal to the LUMO. It has been proposed [71] on the basis of semi-empirical calculations [72] and experimental evidence [73] that for aryl halides an intramolecular ET from the primarily formed π^* to the $\sigma^*(\text{C–X})$ is responsible for the observed difference in cleavage rates ($k = 10^{10} \text{ s}^{-1}$ for phenyl halides compared with $k = 10^{-2} \text{ s}^{-1}$ for nitrophenylhalides). More precisely, intramolecular $\pi^* \rightarrow \sigma^*$ dissociative ET takes place when the energy of the σ^* orbital is reduced (as a result of bond stretching) to match the energy of the π^* LUMO to which the unpaired electron has initially been transferred [17].

Synthetic aspects

As we have seen above, the rate of bond cleavage can be modulated very readily by the energy splitting between the π^* LUMO and the unoccupied $\sigma^*(\text{C–X})$. Usually the π^* LUMO belongs to an aromatic, heteroaromatic, vinylic, or heterovinylic (e.g. acyl groups) acceptor. Bonds that are frequently cleaved are depicted in Scheme 16.

Common π^* acceptors as redox relays for reductive bond cleavage.

Combine

good π^* acceptors

with good σ^* acceptors: C–Hal, C–O, C–S, C–Se, O–O, Si–Hal

avoiding overlap of the σ^* and π^* orbital system. Intramolecular ET from the π^* radical anion to the σ^* acceptor leads to bond cleavage. Frequent systems are

Scheme 16. Frequently used π^* acceptors that function as redox relays to shuttle electrons to the scissile C–X bonds.

Scheme 17. Four reductive C–Hal bond-cleavage reactions are used in the quadruple $\text{S}_{\text{RN}}1$ reaction to assemble **10** [80].

Frequently, bond cleavage is used for $\text{R–Hal} \rightarrow \text{R–H}$ dehalogenations [74], and the formation of carbanions [75]. More seldom encountered are reactions of π^* acceptors that have the σ^* bond spatially well separated and that depend on long-range ET. Such a situation occurs in phenyl-substituted alkyl chlorides [76], and bridgehead halides [77] with various redox relay functions (e.g. a nitroaryl group) [78].

π^* Haloacceptors and related systems play a prominent role in $\text{S}_{\text{RN}}1$ reactions [2b] of aryl halides [79, 80], hetaryl halides [79c, 81], and vinyl halides [82]. A spectacular example of the use of such acceptors is the macrocycle synthesis by a quadruple $\text{S}_{\text{RN}}1$ reaction depicted in Scheme 17 [80].

C–C bond cleavage is readily possible with nitrile radical anions as a shuttle [83]; C–N bond cleavage is rare, but has been effected in phenyl-substituted dimethylanilines [84], some benzenesulfonamides [52], and by using benzotriazole both as the π^* acceptor and as the anionic leaving group [85]. C–O or C–S bond cleavage can readily be accomplished in reductions of the type $\text{R–O} \rightarrow \text{R–H}$ [86] and lithium carbanion generation [23]. C–S bond cleavage in aromatic polysulfones [87] and alkenyl phenyl sulfones [88] can, moreover, be regarded as originating from π^* acceptors. Other bond-cleavage processes have been recognized—for example in the cathodic cleavage of S–P [89], N–S (in aryl azo sulfides) [90], and Si–O bonds [91].

Kinetic and thermodynamic aspects

C–Hal bond cleavage

Recent work [72b, d] has demonstrated that for a variety of halonitrobenzene radical anions there is a correlation between the experimental rate constants (spanning eight orders of magnitude) and $\Delta E_{\sigma^*, \pi^*}$. If the scissile bond of interest does not change its σ^* LUMO energy significantly within a series of analogous compounds, changes in the energy gap $\Delta E_{\sigma^*, \pi^*}$ can be experimentally accessed through $E_{(\text{RX}, \text{RX}^{\bullet-})}^\circ$. As a result, linear correlations between $\log k$ and $E_{(\text{RX}, \text{RX}^{\bullet-})}^\circ$ were obtained for aryl chlorides and bromides [17]. Moreover, a correlation of $\log k$ (C–Br bond cleavage) with σ was found in $\text{YC}_6\text{H}_4\text{–Br}^{\bullet-}$ ($\rho = -17.9$) [66].

With regard to different leaving groups and the substitution pattern at the aryl group several general statements are possible [71, 72a, 92]. The dissociation rate constant of $\text{Ar–X}^{\bullet-}$ varies considerably with the nature of the halogen ($\text{I} > \text{Br} > \text{Cl}$)

and its position relative to a second substituent ($o > p > m$). Comparison of cleavage rates reveals the order of reactivity $\text{CN} > \text{CH}_3\text{C}(=\text{O}) > \text{NO}_2$. For a series of compounds with similar structures the intrinsic activation barrier changes with the thermodynamic component [93], in accordance with the Savéant model [17, 40]. Solvent effects on the cleavage rate constants of π^* radical anions are much better understood, as a result of recent investigations [94]. Earlier results implied specific solvation of the transition state, but recent work has emphasized the dominant role of solvation of the leaving group. It was, moreover, shown that solvent effects, which can be described by the Pekar factor, determine the intrinsic rate constant [94].

By use of a series of 1-aryl- ω -haloalkanes [95a] and 1-aryl- ω -haloalkanes [95b] intramolecular ET between the π^* radical anion site and the distal σ^* (C–X) acceptor was evaluated for longer distances. The correlation with the acceptor number of the solvent indicates that the negative charge is more localized in the transition state than in the initial radical anion [95b]. Notably, rate constants for the dissociation of $\text{Ar-Cl}^{\cdot-}$ show the same correlation with solvent polarity as aryl- ω -haloalkanes [95b]. Experimental and theoretical investigations on ω -halo-1-alkene $^{\cdot-}$ [96] and phenyl-substituted 4-benzoyloxy-1-methylcyclohexylbromide $^{\cdot-}$ [97] shed further light on intramolecular dissociative ET processes.

C–X bond cleavage

C–O bond cleavage rates have become accessible through kinetic investigations of diphenyl ether ($k = 4 \times 10^5 \text{ s}^{-1}$) [98] and of trifluoromethoxybenzenes (4-CN: $k = 4 \times 10^3 \text{ s}^{-1}$, 4-H: $k = 3 \times 10^7 \text{ s}^{-1}$). Interestingly, when the leaving group properties of methoxide and chloride were compared [99], cleavage was rapid when attached to a phenyl ring, but much slower when attached to a 4-cyanophenyl group. The C–S thioether bond is more readily cleaved than the C–O bond [100].

Cleavage of other bonds

Rate data for cleavage of other bonds are rare. According to electrochemical investigations, S–S bond cleavage in diphenyldisulfide $^{\cdot-}$ proceeds at $5 \times 10^8 \text{ s}^{-1}$, whereas that of dialkyldisulfides is slightly slower [101].

1.4.3 Synthetic, Kinetic and Thermodynamic Aspects of Oxidative Bond Cleavage

Bond cleavage after oxidation of σ donors

In comparison with the rich chemistry of σ^* radical anions the synthetic utility of σ radical cations is quite restricted, because pure σ donors are mostly limited to Si–Si, C–Si, C–Ge, and C–Sn functionalities (Scheme 18). Only strained carbocyclic compounds [119] have low ionization energies (IE) that make them readily accessible $\sigma(\text{C–C})$ and $\sigma(\text{C–H})$ donors, but they are of limited synthetic use. In contrast, $\text{Me}_3\text{M–MMe}_3$ ($\text{M} = \text{Sn, Ge, Si}$; IE s ranging from 8.0 to 8.3 eV) [5] and Me_4M ($\text{M} = \text{Sn, Ge, Si}$; IE s ranging from 8.9 to 9.8 eV) [5] are, in general, better donors

Common σ donors for oxidative bond cleavage

C–Si, C–Ge, C–Sn, Si–Si, C–N (in azo compounds)

Scheme 18. Frequently encountered σ donors that undergo efficient oxidative bond cleavage.

than terminal alkenes (e.g. propene has a $IE = 9.73$ eV) [5], which makes them attractive for oxidative cleavage.

Synthetic aspects

Whereas C–H bond cleavage has been used only rarely, e.g. in adamantane [103], C–C bond rupture is more common, but only in strained carbocycles [104–106]. C–N bond cleavage is observed in azoalkane $^{++}$ decomposition [106d], although little synthetic use has been elaborated [107]. In contrast, C–Sn bond cleavage in alkylstannanes has been developed into a novel alkylation of α,β -unsaturated ketones [108] and a versatile alkylation of electron-poor olefins [109]. Oxidative Si–Si [110] and Ge–Ge bond cleavage [102] have also found use.

Scheme 19. Oxidative C–C bond cleavage in housane **11** leads to the formation of diquinane **12** [106c].

Kinetic and thermodynamic aspects

Whereas the rather strong donor qualities of the above electrophores can readily be quantified by the corresponding ionization energies [5, 111], very little is known about the thermochemical data, except as a result of calculation [112, 113]. Fragmentation of Me_3MR^{++} ($M = Si, Sn$; $R = Me, i\text{-}Pr, \text{allyl}, \text{benzyl}, Ph$) is endothermic for all R and occurs in the order $i\text{-}Pr \geq Me > \text{allyl} > \text{benzyl} > \text{phenyl}$ and $M = Sn > Si$ [113]. C–Sn bonds can be cleaved efficiently through intramolecular assistance by a carbonyl group or heteroatoms [114], as is also known for Si–Si bond scission [115]. Sn–Sn [116], Sn–Ge [116], Sn–Si [116], and Ge–Ge [117] bond-cleavage reactions roughly follow the qualitative order: $Sn\text{--}C \gg Ge\text{--}Ge > Si\text{--}Si$ [117].

C–H and C–C bond cleavage in σ radical cations is feasible, but not a versatile option for synthetic use because of the very high oxidation potentials. Deprotonations in alkane radical cations have strongly negative Gibbs energies, with strong preference for tertiary over secondary or primary C–H bonds [118]. C–C bonds are selectively weakened in strained carbocycles [119].

Bond cleavage after oxidation of ($\sigma + \pi$) or ($\sigma + n$) donors

Analogous to the situation of ($\sigma^* + \pi^*$) acceptors, a donor can be composed of two interacting σ and π (or n) electrophore subunits [120]. For stereoelectronic reasons [121] bond weakening in ($\sigma + \pi$) or ($\sigma + n$) donors is most often encountered between the α and β atoms (with respect to the π or n electrophore, Scheme 10).

Synthetic aspects of ($\sigma + \pi$) donors

C–H deprotonation is frequently encountered at the benzylic position of aromatic [122] and heteroaromatic [123] systems (e.g. in deprotections [124]), in bisallylic systems [125], but less often in allylic functionalization [126]. To compete with other pathways C–C bond scission often needs an extra driving force which is available in strained cyclic systems [127]. Unstrained systems require the assistance of radical- and cation-stabilizing groups to reduce the C–C bond-dissociation energy [128].

good π donors

with

and allow for good overlap of the σ and π orbitals such as in

Scheme 20. Frequently used ($\sigma + \pi$) donors that undergo oxidative bond cleavage.

The proper use of a strong electrofugal group X^+ ($X = SiR_3, SnR_3, SR$) facilitates highly chemoselective bond scission [129], as in many C–Si [130, 131] and C–Sn cleavage reactions [132]. When alternatives are lacking oxidation of sulfides often results in the oxidative cleavage of the C–S bond [133]. O–H deprotonation is a key step in the oxidative transformation of phenols [134] (Scheme 21) and enols [135]. Much less used are other scissions, e.g. Si–Si bond cleavage [136].

Synthetic aspects of ($\sigma + n$) donors

C–H deprotonation plays an important role in the α -functionalization of alcohols [138], amines [139] + related N -functionalities [140], ethers [141], and sulfides [142]. N,O -acetals are versatile precursors to N -acyliminium intermediates [143].

Because cation stabilization makes an important contribution, N-, S-, and O-substituents are often used to support C–C bond cleavage [109, 144]. C–C bond scission is readily achieved in strained carbocyclic [145] or heterocyclic [146] ring systems, with many examples stemming from cyclopropyl sulfides [147].

Scheme 21. O–H Deprotonation is the key step in the oxidation of phenol **13** to the tricyclic product **14** [137].

C–Sn [148] and C–Si [121, 149] bond cleavage has developed into a versatile synthetic method for adding functionality α to nitrogen, oxygen and sulfur centers. C–Si bond cleavage is known to be induced by nucleophiles such as pyridine [150] and methanol, and stereoselectivities have been interpreted as indicating that C–Si bonds can even be attacked by a double bond system [151].

Scheme 23. C–Si bond cleavage assisted by the neighboring double bond [151b].

*Kinetic and thermodynamic aspects***C–H bond cleavage**

Removal of an electron generally brings about significant thermochemical C–H bond weakening both in $(\sigma + \pi)$ radical cations (i.e. deprotonation in the benzylic position [152]) and $(\sigma + n)$ radical cations (i.e. deprotonation at the α -carbon of amines [153, 154], ethers [155], and thioethers [156]). The kinetic acidity of benzyl radical cations is rather well understood [152d, 157, 158], although occasionally an addition–elimination route was favored over direct proton transfer [159]. For alkyl arene radical cations [160] a linear relationship has been established between $\log k_{\text{dep}}$ and thermochemical acidity [157].

Likewise, the biologically important C–H deprotonation [161] of amine radical cations has been extensively studied [162], with the kinetic acidities paralleling the thermodynamic $\text{p}K_{\text{a}}$ values [163]. C–H deprotonation of thioethers has also been studied, but more rarely [164].

C–C bond cleavage

Bond dissociation data [165] indicate that C–C bond cleavage can only occur with appropriate substitution at the carbon centers (alkyl, aryl, hydroxy, siloxy, alkoxy) [166] to stabilize the resultant radical and cationic intermediates [152e]. Reasonable prediction of C–C bond cleavage of $(\sigma + \pi)$ radical cations can be made on the basis of linear correlation between kinetic and thermodynamic data for 1,2-biarylethanes [167]. Activation data correspond closely to the experimental ΔG° values [60]. Importantly, C–C bond-cleavage reactions in strained-ring systems can be induced by nucleophiles leading to inversion of configuration at the carbon center [168]. $(\sigma + n)$ radical cations equally can undergo C–C bond cleavage at a sufficiently high rate [169] (even decarboxylation [170]).

C–X bond cleavage

Monomolecular C–X bond cleavage energies are accessible by thermochemical cycle calculations; such bond dissociation processes are often induced by nucleophiles, at least with $\text{X} = \text{SiR}_3$ [163, 171]. As a consequence, rates are much faster than expected on the basis of thermochemical data. Detailed data are available for aniline radical cation desilylation [170].

C–N bond cleavage in cyclic azoalkane $^{2+}$ with expulsion of N_2 is apparently very rapid, because only follow-up products were detected [172]. In contrast, C–S bond cleavage in benzyl phenyl sulfide $^{2+}$ is rather slow with $k \approx 10^3 \text{ s}^{-1}$ [164].

O(N)–H bond cleavage

In such systems, C–H deprotonation—if feasible at all—cannot usually compete with O–H deprotonation. Whereas thermodynamic $\text{p}K_{\text{a}}$ values are available [173], kinetic data are rather scarce [174], despite the importance of such processes. Very

recently, the rate constants for deprotonation of phenol radical cations by water were measured to be $(0.6\text{--}6) \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$. Consistent with the $\text{p}K_{\text{a}}$ values, the 2-methoxyphenol radical cation is more reactive than the 4-methoxy derivative [175].

Cleavage of other bonds

Other bond cleavage (O–Si [176], O–Sn [177], O–C [178], O–P [179], O–Ti [176b, 180], O–Zr [181], S–C [182], Si–Si [183]) can be readily set up in radical cations for synthetic use and in several instances kinetic data are known. Rapid O–C bond cleavage might even occur in the antioxidant action of 7,8-diacetoxy-4-methylcoumarin [184].

Bond cleavage after intramolecular ET via π or n redox relays

Although the analogous reaction mode is frequently observed with radical anions, at present this seems to be largely a *terra incognita* in radical-cation chemistry. We would, therefore, like to propose the combination of readily scissile σ donors, e.g. C–Sn, C–Si, and the Group IV M–M bonds ($\text{M} = \text{Si}, \text{Ge}, \text{Sn}$), with good π donors in the same molecules. Because the π donor must be more electron-rich than the σ donor, electron-rich π donors such as ferrocene-, amino-, and alkoxy-substituted phenyl groups, and larger aromatic systems might be appropriate. Such a system is, for example, realized in the C–Sn bond cleavage of trimethylphenylstannane $^{+}$ [113]. Other examples might include methylenecyclopropane [185], which is known to effect rapid cleavage of the C–C bond [186], and of the Ge–O bond in diger-moxanes [187].

The elegant synthesis of the harringtonine alkaloid skeleton might involve the photoinduced oxidation of an electron-rich phenyl group that acts as a redox relay by accepting an electron from the $\sigma(\text{C}–\text{Si})$ donor [188].

Scheme 24. Formation of parts of the harringtonine alkaloid skeleton via C–Si bond cleavage [188].

1.5 Reductive and Oxidative Bond-formation Reactions

1.5.1 General Principles of Bond Formation

Although the bond-cleavage reactions described above might also lead to bond formation *via* a follow-up intermediate, we would like to discuss in the ensuing section bond formation right at the stage of the radical ion. Again, we recognize very similar reaction motifs in both radical-anion and radical-cation chemistry (cf. Schemes 5 and 25).

1.5.2 Synthetic, Kinetic and Thermodynamic Aspects of Reductive Bond-formation

Bond formation at the radical anion stage (Scheme 25) usually occurs either by reaction with an electrophile (proton, cation, unsaturated electron-poor system) or with another odd-electron species (charged or neutral radical).

Reactions of π^* radical anions with closed-shell systems

Synthetic aspects

One of the most frequently encountered reactions is that with proton sources, as observed with arenes (Birch reduction) [189], aldehydes [190], alkynes [2d], fullerenes [191], ketones [192] (even enantioselective protonation of ketyl radical anions [193]), nitriles [194], nitro [195] and nitroso compounds [196], and olefins [197]. Protons are often replaced as electrophiles by trialkylsilyl chloride [198].

C-C bond formation in inter- or intramolecular additions starting with olefin [199, 200], ketyl [201] (generated by PET [202], chemical or cathodic [24, 203] reduction) [204, 205] or imine radical anions [206] has become a versatile method. In general, the intramolecular addition is highly suitable for the construction of five membered rings, less so for six-, and not effective for seven-membered ring formation.

Scheme 26. Stereoselective bisimine cyclization via radical anion intermediates [206b].

Kinetic and thermodynamic aspects

Protonation

Protonation becomes a rapid reaction in protic solvents and in the presence of acids, as demonstrated for, e.g., *n*-butyl acrylate in aqueous solution [207], methyl acrylate in EtOH [208], cinnamates in the presence of phenol in DMF [209], and benzaldehyde in ethanolic buffer solution [210]. Rate constants for protonation of aromatic radical anions (anthracene [211], naphthalene, 2-methoxynaphthalene, 2,3-dimethoxynaphthalene) by a number of proton donors including phenols, acetic acid, and benzoic acids in aprotic DMF were found to vary from $5.0 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ (for anthracene, in the presence of *p*-chlorophenol) to $6.2 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ (for anthracene, in the presence of pentachlorophenol) [212]. For dimedone, PhOH, or PhCO₂H the rate of protonation depends on the hydrogen-bond basicity of the solvent and increases in the order DMSO < DMF << MeCN [213].

When the substrate was more difficult to reduce the rate of protonation of alkyl cinnamates in the presence of phenol in DMF [209] increased. For aryl cinnamates the competing rate-determining dimerization of the radical anions is predominant [214]. In MeOH proton transfer occurs as a monomolecular reaction with the hydrogen-bonded radical anion complex (first-order rate constant k_{prot} varies from $2.9 \times 10^2 \text{ s}^{-1}$ to $3.5 \times 10^3 \text{ s}^{-1}$) [215].

Faster protonation rates were observed in the self-protonation of aromatic carboxylic radical anions ($k_{\text{prot}} > 10^6 \text{ M}^{-1} \text{ s}^{-1}$) [216] and (*R*)-(-)-1,1'-biphenyl-2,2'-diyl hydrogen phosphate radical anion ($k_{\text{prot}} = 5.7 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) [217].

Reaction with other electrophiles

Kinetic studies of the reaction of CO₂ with radical anions generated from dialkyl fumarates and maleates showed that C–C bond formation was the rate-determining step. The pseudo first-order rate constants, k_{CO_2} , for fumarate radical anions in CO₂-saturated DMF were found to vary between 0.35 and 1.5 s⁻¹ and to decrease in the same order as observed for dimerization [218]. Rate constants for maleates (k_{CO_2} varied from 32.0 s⁻¹ to 18.0 s⁻¹) were higher. Rather slow is the coupling of CO₂ with the 4-keto isophorone^{•-} in MeCN ($k_{\text{CO}_2} = 0.35 \text{ s}^{-1}$) [219].

Aromatic radical anions and alkyl halides can react either by ET or direct S_N2 [95a, 220]. The S_N2 reaction depends on the steric requirements of the substrate and the magnitude of the driving force for the ET process [221]. In general, with increasing standard potential of the aromatic compound or decreasing ability of the substrate as electron acceptor, the S_N2 mechanism becomes more important.

Reactions of π^* radical anions with open-shell systems

Synthetic aspects

The coupling of two radical anions is frequently realized in the reductive dimerization of olefins with different groups R, for example R = CN (e.g. acrylonitrile [234]), C(=O)OR [198b, 237], C(=O)X [222], Ph [223], NO₂ [224], and SO₂Ph [225]. Diastereoselective and enantioselective dimerizations are reported for cinnamic esters [226] and oxazolidones [227], respectively.

On the other side, coupling of radical anions with radicals is a key step in the electrochemical reductive *t*-butylation of aromatic compounds [228], in the photo-NOCAS reaction [229], and for other combinations [87].

Scheme 27. Radical anion–radical coupling in the photo-NOCAS reaction [229].

Radical-anion and radical-cation intermediates, for example, react with each other after PET in donor–acceptor systems. After proton reorganization they undergo cyclization to provide a direct synthetic route to macrocycles and *N*-heterocycles with a variety of ring sizes [230]. Cycloadditions *via* radical ion pairs [231] and the C–C bond formation between C₆₀ and *N,O*-ketene acetals [232] also fit this category.

Kinetic and thermodynamic aspects

Intermolecular reactions of π^* radical anions with electron-poor olefins often proceed quite sluggishly. As a consequence, radical anion electrohydrodimerization (EHD) and radical anion–radical reactions are frequently encountered during electrochemical reduction when the radical concentration is rather high.

Dimerization of activated olefins

In general, the cathodic reduction of electron-deficient olefins generates a π^* radical anion which undergoes radical anion–radical anion dimerization to form the dianion dimer which undergoes protonation and/or cyclization. Several investigations

[233] have been performed on reductive dimerization; the best known example is the production of adiponitrile from acrylonitrile [234]. The initial step in the EHD is a rapidly established equilibrium between two radical anions and a dimer dianion; this has been extensively studied for cinnamates [235], fumarates [236], and maleates [237].

For dimerization of methyl and ethyl cinnamate the equilibrium constants were estimated to be 53.1 and 109.0 M⁻¹, respectively [238]. In solvents of low acidity (acetonitrile, DMF, alkaline ethanol) [235] the radical anion dimerization step was found to be rate-determining ($k \approx 5 \times 10^3$ M⁻¹ s⁻¹) depending on the structure of the alkyl group of the cinnamic ester moiety [239] (e.g., for electron-donating R = Bu^t, $k_{\text{obs}} = 4.1 \times 10^2$ M⁻¹ s⁻¹; for electron-withdrawing R = 4-NC-C₆H₅, $k_{\text{obs}} = 5.7 \times 10^4$ M⁻¹ s⁻¹). Rate studies indicate that complexation with water is crucial for the radical anion–radical anion coupling step of ethyl cinnamate ($k = 5.4 \times 10^2$ M⁻¹ s⁻¹ in DMF containing 0.28 M H₂O; $k = 1.4 \times 10^2$ M⁻¹ s⁻¹ in dry DMF [236]). As a consequence, stereoselectivity in cinnamic ester coupling could be controlled by appropriate selection of the solvent. In slightly wet DMF dimerization is relatively slow and stereoselective—involving two radical anions with a hydrogen-bonded water molecule serving as a template—whereas in MeOH two neutral radicals are involved in the rapid and unselective dimerization.

The dimerization rate constants of dialkyl fumarates ($k = 25$ – 120 M⁻¹ s⁻¹) [236] decrease with increasing steric hindrance of the alkyl group and prove to be significantly smaller than those of fumaronitrile ($k = 7 \times 10^5$ M⁻¹ s⁻¹) [240]. The electrochemically generated dimethyl maleate^{•-} undergoes rapid *cis*–*trans* isomerization to the dimethyl fumarate^{•-} then rapid radical anion dimerization [241]. In comparison, the EHD rate constant for 4-methylcoumarin ($k = 1.8 \times 10^5$ M⁻¹ s⁻¹) proved similar to that of a relatively fast cinnamate (4-cyano; $k = 5.7 \times 10^4$ M⁻¹ s⁻¹) [242].

Dimerization of arenes and heteroarenes

The dimerization of anthracene^{•-} has been studied extensively [243, 244]. With strongly electron-withdrawing substituents at position 9 the radical anions undergo reversible dimerization in aprotic solvents such as DMF, MeCN, propylene carbonate, DMSO etc. followed by rate determining σ bond formation to furnish the stable dimer dianion [245]. In DMF k_{dim} were found to decrease in the order NO₂ ($k_{\text{dim}} = 1.6 \times 10^6$ M⁻¹ s⁻¹) > CHO ($k_{\text{dim}} = 3.1 \times 10^5$ M⁻¹ s⁻¹) > CN ($k_{\text{dim}} = 1.3 \times 10^5$ M⁻¹ s⁻¹).

Reductive dimerization of benzene [246], cyano biphenyl ether [247], pyridine [248], and acridine [249] derivatives has also been investigated. Radical anions of diesters of pyridine and benzene undergo rapid reversible dimerization ($k_{\text{dim}} = 10^3$ – 10^4 M⁻¹ s⁻¹) [250].

Dimerization of aldehydes, ketones and related systems

In general, reductive generation furnishes a ketyl radical anion which undergoes radical–radical coupling to form the dimer dianion [251]. This dimerization was found to be faster than the reaction of the radical anion with the parent molecule (e.g. for of *p*-cyanobenzaldehyde: 28.6 M⁻¹ s⁻¹ compared with 1.45 M⁻¹ s⁻¹) [252].

Kinetic studies have revealed that aliphatic ketyl radical anions are very short-lived compared with aromatic (half life of acetone^{•-} in aqueous 2-propanol is 72 μ s, whereas that for acetophenone^{•-} is 1.5 ms) [253]. The reductive dimerization of simple aromatic aldehydes has been studied in aprotic solvents, with the second order rate constant being larger in acetonitrile than in DMF, because of ion-pair effects [254]. Electron-withdrawing substituents reduce the speed of dimerization (benzaldehyde^{•-}: $k = 2.4 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$, *p*-cyanobenzaldehyde^{•-}: $k = 5 \text{ M}^{-1} \text{ s}^{-1}$) [255], whereas protic solvents lead to protonation before dimerization [256].

In imine reductions rapid equilibration of dimeric dianions and the precursor radical anions leads to the thermodynamically more stable isomer [257]. In the reductive coupling of salicylideneanilines, however, rate-determining C–C bond formation is preceded by intramolecular H-bridging [258].

Reaction with neutral radicals

Few rate data have been reported for the coupling of radical anions with alkyl radicals [259]. In general, coupling is rapid with rate constants approaching the diffusion limit (1-hexenyl radical + naphthalene^{•-}: $k_2 = 2.4 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ in 1,2-dimethoxyethane) [260]. Although the rates of coupling of alkyl radicals with aromatic radical anions are found to vary slightly in the order primary > secondary > tertiary, the small activation energy is not sensitive to structural differences between the alkyl radical and in the aromatic substrate or to variations in SOMO–SOMO energies [261].

1.5.3 Synthetic, Kinetic, and Thermodynamic Aspects of Oxidative Bond-formation

Reactions of π radical cations with closed-shell systems

Common π donors for oxidative bond formation.

Use

good π donors

but avoid any scissile bonds at the periphery of the π system, such as

C–Si, C–Sn, $\overset{\cdot\cdot}{\text{X}}\text{--}\overset{\cdot\cdot}{\text{H}}$, $\overset{\cdot\cdot}{\text{X}}\text{--}\overset{\cdot\cdot}{\text{Si}}$

Sometimes even cleavage of

C–C (in strained systems) and C–H bonds

may interfere with bond formation processes

Scheme 28. Frequently used π donors for oxidative bond-formation reactions.

Synthetic aspects

Intermolecular reactions involving attack of *n*-nucleophiles (even F^-) [262] at π radical cations include reactions at alkenes [263], allenes [264], aromatic systems

[265], enol esters [266], enol ethers [267], fullerenes [268], benzofurans [269], dienes [270, 271], furans [272], pyrrolidines [273], and ketene imines [274]. These reactions usually proceed by *anti*-Markovnikov addition [275]. C–C bond formation is possible by reaction with cyanide [264]. Truly spectacular examples are derived from PET cascade cyclizations [276], as demonstrated in a short biomimetic route to the steroid system **25** (two out of 256 stereoisomers) [277].

Scheme 29. Biomimetic cascade cyclization of **24** to steroid ring system **25** [277].

Likewise, *n*-nucleophiles react well in intramolecular cyclizations to trap olefin and arene radical cations [278].

Because both radical–nucleophile and radical–radical coupling (electropolymerization [316]) can occur under anodic conditions mechanistic differentiation is often difficult. Under chemical oxidation [279b] and PET conditions [279a], however, only radical–nucleophile coupling is encountered. Intermolecular [280] and intramolecular [281] C–C bond formation used for biomimetic atroposelective coupling [282] and for natural product synthesis [283] is nowadays a well-established synthetic tool.

Kinetic and thermodynamic aspects

Although addition of a nucleophile to a π radical cation seems to be a straightforward process, several mechanistic scenarios [284] (e.g. the disproportionation, complexation, and half-regeneration pathways) that depend on the reactants need to be considered [285]. It has, moreover, been stressed that for protic nucleophiles such as alcohols and water, deprotonation of the primary adduct is important [286]. As a consequence, the rational design of bond-forming reactions requires deeper understanding of mechanistic matters.

Extensive kinetic data have been collected over the last decade especially for substituted arylanthracenes [287], dienes [288], styrenes [289], and psoralen [290]. Combinations of π radical cations and *n*-type nucleophiles are very rapid processes that approach the diffusion controlled limit for anionic nucleophiles. Primary

amines were found to add to 9-phenylanthracene radical cation with second-order rate constants in the range 8×10^6 to $3 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$. The rates increase with increasing amine basicity and decreasing steric requirements [287]. If, however, the amines become too strong donors (e.g. tertiary amines and anilines) they might react with the radical cation by ET [291]. Less studied are reactions with protic nucleophiles that occur according to the deprotonation mechanism. In line with nucleophilicity data [292], bond formation with water and alcohols is much slower than with amines and pyridines [286, 289].

The reaction of π radical cations with π nucleophiles usually leads to C–C bond formation, a reaction that can be very fast (cf. pericyclic reactions also), as in the oxidative dimerization of triphenylamine ($k = 1\text{--}10 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$) [293]. Hence, such a reaction mechanism can even operate in anodic oxidations (4-methoxybiphenyl [294], tetrahydrocarbazole [295], 4,4'-dimethoxystilbene [296] and 9-methoxyanthracene) [297], where the radical cation concentration is very high.

Reactions of π radical cations with open-shell systems

Synthetic aspects

π Radical cations react readily with stable radicals, e.g. oxygen [298], superoxide [299] or NO_2 [300], and short-lived radicals (as detected in the charge transfer nitration [301] of electron-rich aromatic systems with tetranitromethane) [302]. Moreover, PET in general leads to intra- [303] or intermolecular [304] radical ion pairs [305], but direct bond formation between organic radical cations and radical anions is rare. It might play a role in PET Paternò–Büchi reactions [306], and in related PET cycloadditions [307]. If the radical anion site of an intramolecular radical ion pair is designed to lose an anion, efficient protocols to radical cation–radical combinations can be installed.

Scheme 30. Radical cation–radical coupling after intramolecular PET and loss of chloride at the radical anion site [305a].

Radical cation–radical cation coupling [308] is often observed during anodic oxidations when their concentration is sufficiently high; the capacity of π radical cations to undergo atom abstraction reactions, e.g. of fullerene $^{+\bullet}$ [309], has little significance only.

Kinetic and thermodynamic aspects

Reactions with stable radical species, e.g. oxygen and NO_2 , occur readily, although oxygenation rates of aryl olefin radical cations (ca $10^6 \text{ M}^{-1} \text{ s}^{-1}$ [310]) are two or three orders of magnitude slower than those of neutral radicals with oxygen [311]. The polar effect in such reactions is remarkable. Whereas *trans*-stilbene $^{\bullet+}$ has little reactivity towards oxygen, derivatives with a *p*-MeO group react at $k = 1.2\text{--}4.5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ [312]. Much more rapid is the reaction of stilbene $^{\bullet+}$ with superoxide ($k = 4.1 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$) [310].

Reactions that include the dimerization of two radical cations are, for example, those of anethole [313], pyrroles [314], oligopyrroles [315], thiophenes [316], oligothiophenes [317], diphenylamine [318], triphenylamine [319], *N,N*-dimethylaniline [320], and diphenylpolyene [321].

Reactions of *n* radical cations with closed-shell systems**Common *n* donors for oxidative bond formation.****Use****good *n* donors**

but avoid any scissile bonds at the periphery of the π system, such as

Sometimes even cleavage of

C-C (in strained systems) and C-H bonds

may interfere with bond formation processes

Scheme 31. Commonly used *n* donors for oxidative bond formation.

Synthetic aspects

Whereas nitrogen-centered radical cations are prone to C-H, C-C bond-cleavage reactions, $\text{R}_3\text{P}^{\bullet+}$ and $\text{R}_2\text{S}^{\bullet+}$ suffer predominantly nucleophilic attack [322, 323]; few exceptions have been reported to date. This reaction plays an important part in the formation of oxygenated derivatives (P [324], S [325]), C-S [326], S-S, and Se-Se bond formation [327], and in removing sulfur-protecting groups [328–330].

Whereas intermolecular attack of a π nucleophile is rather rare [331] (e.g. disulfide $^{\bullet+}$ + arene [332], and diselenide $^{\bullet+}$ + dienes [333]), intramolecular cyclizations of amine radical cations have been useful in the preparation of five-membered rings [334].

Hydrogen abstraction is the key factor in the intramolecular radical functionalization step of the Hofmann–Löffler–Freitag reaction (Scheme 32) [335].

Scheme 32. Successful preparation of pentacycle **29** [336] via the Hofmann–Löffler–Freitag reaction.

Kinetic and thermodynamic aspects

Kinetic data are very scarce and available mostly for amine, phosphane [337], and sulfide [338] radical cation reactions with nucleophiles. In intermolecular reactions, phosphane radical cations react with sulfur nucleophiles [339], $k = 10^5\text{--}10^7 \text{ M}^{-1} \text{ s}^{-1}$, following the same reactivity pattern as with π radical cations [289]. Cyclization rate constants for the attack at double-bond systems are faster than those of the neutral radicals, as shown for dialkylamine radical cations [340] ($k = 6 \times 10^5\text{--}1 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$).

Reactions of n radical cations with open-shell systems

Synthetic aspects

Oxygen reacts readily with aromatic sulfides [341], *N*-methionyl peptides [342], 1,3-dithianes [343], aziridines [344], and phosphorus [345] compounds after oxidation. On the other hand, aryl radicals are involved in the ET reaction of trivalent phosphorus compounds with aromatic diazonium salts [346].

Kinetic aspects

Although the homogeneous reaction of sulfide $^{•+}$ with oxygen has been accomplished at high O_2 pressures only [347], the spontaneous reaction in a zeolite was recently monitored kinetically [348]. The very large rate constant for the reaction between dimethylsulfide $^{•+}$ and superoxide, $k = 2.3 \times 10^{11} \text{ M}^{-1} \text{ s}^{-1}$, can be interpreted in terms of rapid ET rather than radical–radical coupling [349]. Rates are also known for the reaction of phosphane $^{•+}$ with oxygen [339].

1.6 Pericyclic Reactions

1.6.1 General Principles of Pericyclic Reactions

Per definitionem, pericyclic reactions proceed in a concerted manner, i.e. bond cleavage and bond formation occur simultaneously. Recent high-level calculations

on radical cation Diels–Alder reaction have, however, put the stepwise [350] and concerted [351] cycloadditions close in energy whereas experimental evidence (mostly [352] stereospecific! [353]) argues for concertedness. Stereospecific retro-Diels–Alder fragmentation has, moreover, been observed in the gas phase [354].

1.6.2 Synthetic, Kinetic and Thermodynamic Aspects

Radical anion pericyclic processes

Synthetic aspects

Although cycloadditions have frequently been observed in radical-cation chemistry, this reaction mode is apparently very rare in radical-anion chemistry because of the electron repulsion term. Few examples are known of Diels–Alder dimerizations [355], [2 + 2] cycloadditions [356], retro-[2 + 2] cycloadditions [357], and cyclo-trimerizations [358]. Equally, little is known about electrocyclic reactions, despite their interesting stereochemical course [359].

Although the synthetic utility of radical anion pericyclic processes is still to be explored, the recently disclosed intermediacy of radical anions in metathesis reactions with Grubb's catalyst [360] should ignite the search for further examples of this interesting class of reactions.

Kinetic and thermodynamic aspects

To the best of our knowledge no experimental kinetic and thermodynamic studies have been performed on radical anion pericyclic processes. Interesting structural information has, however, been obtained for some [2 + 2] cycloadduct^{•−}, e.g. 4N/5e radical anions [361].

Radical cation pericyclic processes

Synthetic aspects

Since their original discovery [362] pericyclic radical cation reactions have been developed for various synthetic formats. The methodology nowadays is most advanced for intra- [363] and intermolecular Diels–Alder cycloadditions [364], and

Scheme 33. Only two out of 32 possible isomers of **32** are formed in this highly peri-, chemo-, regio- and stereoselective radical cation Diels–Alder cycloaddition [365b, c].

Scheme 34. Preparation of porphyrin **34** initiated through electrocyclic ring opening of four azirine radical cations to 2-azaallenyl radical cations [373c].

wide variations in the dienophile [365] (cf. allene **31**) and the diene [366] have been realized. Likewise, several examples are known of other cycloadditions ([2 + 2] [367], with diazomethane [368] or osmium tetroxide [369], epoxidation [370], cyclopropanations [371]) and cycloreversions [372].

An exciting cycloaddition which is not pericyclic in nature has been developed on the basis of PET opening of azirines to 2-azaallenyl radical cations [373]; these add readily to substrates such as imines and acetylenes. This paves the way for the synthesis of imidazoles [373a, e], heterophanes [373b, e], and even porphyrins (cf. the preparation of **34**) [373c, e].

Many classical pericyclic reactions, for example the Cope [374, 375], Claisen [376], vinylcyclobutane [377], vinylcyclopropane [378], and vinylcyclobutanone [365a] rearrangements and the [1, 16] hydrogen shift in an A/D *seco* corrin radical cation [379], can be translated into the radical cation format equally easily. The stereochemical course of these rearrangements has been described as stereospecific in the vinylcyclobutane [377, 380] and Cope [374b] rearrangements but with retention, inversion, and partial loss of the stereochemical integrity in the rearrangement of vinylcyclopropane [381] and vinylcyclobutanone [365a] radical cations.

Kinetic aspects

Recent studies [382] have provided rate data for cycloaddition reactions. Accordingly, steric effects at the electrophile site, and the capacity of the added unsaturated component $\text{RCH}=\text{CH}_2$ to stabilize radicals and cations, play a vital role, the importance of which is reflected in a rate decrease for $\text{R} = \text{Ph} \approx \text{OR} > \text{vinyl} > \text{alkyl}$ by a factor of 100–300. In principle, the observed trends follow those for addition of carbocations to alkenes [292]. A study of the [2 + 1] cycloaddition of 4-methoxystyrene also emphasizes the importance of the rapid one-electron reduction of the intermediate dimer radical cation [383]. A direct view of 4-center 3-electron cyclobutane [384] and bisdiazene-oxide [385] radical cations has been obtained with polycyclic, rigid systems.

1.7 Conclusion

In this brief review we have outlined a unifying concept to promote understanding of primary reaction pathways of radical ions in solution. From the analysis in this review, which is based on (i) identifying the electrophore in a complex molecule and (ii) identifying the character of the electrophore, it has become clear that both radical anions and radical cations undergo analogous reactions with regard to the electrophoric system. Our heuristic concept of relating the reactivity of a radical ion to the relevant electrophore is closely connected to the principle of localized charge as used in mass spectroscopy [386]. Hence, the interested reader will find many analogies in radical ion gas-phase chemistry, an area which unfortunately could not be covered in our present analysis [387].

It is hoped that our guide for predicting the reactivity of radical ions, whether generated by electrolysis, or by chemical or photochemical ET processes, will encourage scientists to devise novel radical-ion reactions for synthetic applications. Because our analysis has aimed at covering synthetically relevant radical-ion transformations, it should be noted that less frequently used reactions, such as *cis-trans* isomerizations, and ET oxidation or reduction of radical ions are not included. One should, moreover, bear in mind that the reactivity of radical ionic intermediates might be heavily influenced by counterion effects [388], a research area which still deserves major attention.

Finally, it can be stated that many reactivity patterns of free radical ions are equally found in oxidative and reductive transformations involving initial inner-sphere ET, such as in reactions with samarium iodide [389], low valent titanium [390] and titanocene complexes [391], manganese(III) [392], and CAN [393].

Acknowledgments

M. K. G. is deeply indebted to the Alexander von Humboldt Stiftung, and M. S. would like to thank all his coworkers whose commitment has made possible the joint contributions in the field of electron transfer activation. Generous financial support over many years from the Deutsche Forschungsgemeinschaft (SFB 347, Schwerpunkt Normalverfahren, Graduiertenkolleg), the Volkswagen-Stiftung, and the Fonds der Chemischen Industrie is gratefully acknowledged.

120. Actually, there is an alternative option that is frequently encountered when a σ donor is flanked on one side by a π donor, on the other by an n donor. In our analysis, we have included this option by assigning such systems either to the $(\sigma + \pi)$ or $(\sigma + n)$ donor class based on the better donor (either π or n).

2 Electron Transfer from Aliphatic and Alicyclic Compounds

Heinz D. Roth

2.1 Introduction

Electron-transfer processes have attracted considerable attention because of their central role in the chemistry of life and as a method for generating interesting intermediates, in the gas phase, in solution, or in the solid state. Photo-induced electron transfer is one of the very few fundamental reaction types known in excited-state organic chemistry. It occurs in the solid state, in solution, and in the gas phase, including the Earth's atmosphere and outer space. The products generated by electron transfer vary with the nature of the substrate and with the medium in which the reaction is conducted. They can be macromolecular 'charge-separated' entities (in the photosynthesis of the green plant), zwitterions, ion pairs, or 'free' radical ions, carrying a positive or negative charge in addition to an unpaired spin. These intermediates can be characterized by a range of spectroscopic techniques and their reactions can be studied conveniently. This chapter deals with electron transfer from saturated chain- or cyclic hydrocarbons, and the structures and reactions of their positively charged radical ions.

Alkanes (Section 2.2) are among the least reactive compounds; their C–H bonds are among the least acidic moieties (highest pK_a values) known. Likewise, *n*-alkanes have very low electron affinities and very high ionization potentials; thus, they are poor electron acceptors and electron donors; it takes significant energies to activate them. For the small-ring compounds, cyclopropane and cyclobutane (Section 2.3), electron transfer occurs with relief of ring strain; these systems are more reactive. Strained bicyclic systems, particularly bicyclo[1.1.0]butane and bicyclo[2.1.0]pentane (Section 2.4), are more reactive still.

Electron transfer from methane is significant because it seems likely that the radical cation and secondary intermediates derived from it (CH_3^\bullet , CH_3^+) played a significant role in the chemical evolution preceding the origins of life. Methane is a probable constituent of early planetary atmospheres and its radical cation has potential significance as an interstellar species.

2.2 Electron-transfer Reactions of Aliphatic Compounds

Alkanes are among the least reactive classes of compound; their C–H bonds are among the least acidic moieties (highest pK_a values) known. Likewise, *n*-alkanes have very low electron affinities and very high ionization potentials; thus, they are poor electron acceptors and electron donors. The molecular anions of *n*-alkanes are even less stable than are those of cycloalkanes (Section 2.3) and their temporary anion states are even shorter lived [1]. Non-dissociative electron attachment requires the dissipation of excess energy by radiation or collision; for simple alkanes, methane through butane, negative ion yields are ca 10^4 times lower than positive ion yields. Typically, electron impact does not result in molecular ions; instead, small fragment ions such as CH^- , CH_2^- , CH_3^- , C_2H^- predominate [2–4]. The adiabatic ionization potentials of *n*-alkanes decrease from 12.61 eV for methane and 11.52 eV for ethane to 10.25 eV for *n*-pentane and 10.13 eV for *n*-hexane and to 9.80 eV for *n*-octane and 9.65 eV for *n*-decane [5]. As a consequence, it takes significant energies to activate these compounds.

In the gas phase, *n*-alkanes are readily ionized upon electron impact (mass spectrometry, MS) or upon He_x impact (photoelectron spectroscopy, PES). The resulting spectra provide information about the molecular ions, for example, on their ease of fragmentation and their fragmentation patterns (MS) [6, 7], whereas the PE spectra reveal the ordering and energies of their molecular orbitals [8]. In solution the high oxidation potentials of *n*-alkanes pose significant difficulties for the generation of their radical cations and render the resulting species highly reactive, although the electron-donor properties improve somewhat with increasing branching (vide infra). Accordingly, these radical cations were long thought to be unstable and decompose by instantaneous deprotonation. Radical cations have become readily accessible only with the advent of halocarbon and noble gas matrix-isolation techniques. The development of these techniques was crucial for the detailed study of *n*-alkane radical cations.

2.2.1 High-energy Irradiation of Matrices

The pioneering work of W. H. Hamill and co-workers established that high-energy photons, such as X-rays or γ -rays, can eject electrons from halogen-containing matrix materials, viz., tetrachloromethane, chlorobutanes, and several Freon mixtures [9–11]. High-energy photons interact with these materials by generating ‘holes’ while ejecting electrons into the matrix (Eq. 1). In the presence of solute molecules (S) of lower oxidation potential than the host (*n*-alkane guests at low concentrations; ca 1 in 10^3), the holes are unstable. A host molecule transfers an electron to the ‘hole’, regenerating the matrix material (Eq. 2). The ejected electrons are ‘solvated’ in the matrix or attach themselves to a halogen-containing molecule (Eq. 3), causing its fragmentation to a halide ion and a free radical (Eq. 4). These processes are without direct consequence for the radical cation; they are mentioned here because they can interfere with the observation of the species chosen for study, or because the halide

ions can scavenge the radical cations to form free radicals (Eq. 5).

The overall procedure, based on a combination of cryogenic techniques, matrix isolation, ionizing radiation, and ESR detection, has become the method of choice for generating and studying alkane radical cations. One note of caution is in order, however. It is generally recognized that the barriers to the rearrangements of radical cations are considerably lower than are those on the parent energy surfaces. Accordingly, some radical cations are unstable in solid matrices and rearrange instantaneously under the conditions of radiolytic generation in frozen matrices. Applications of optical spectroscopy to the study of alkane radical cations are limited. Although this technique is of great importance for studying many organic radical ions, the spectra of alkane radical cations do not fall into an accessible spectral range.

An alternative method of radical cation generation involves photo- or electron-impact ionization of substrates at high dilution (ca 1 in 10^6) during vapor deposition in neon matrices at (ca 5 K) [12]. The radical cations deposited in the matrix owe their stability to the high ionization potential of the matrix material, which is more difficult to oxidize than are *n*-alkanes. This technique has found significant applications and has provided invaluable insights in special cases (Section 2.3); it is not, however, generally accessible and offers only a very limited temperature range for study. Finally, some of the more stable radical cations of highly branched alkanes can be generated in zeolites.

The application of matrix isolation methods has facilitated the generation and study of many radical cations. Early examples of alkane radiolysis generating radical cations include *n*-octane, which produced a species '*n*-C₈H₁₈^{•+}' [13, 14], and the well characterized radical cation of hexamethylethane, reported independently by three different groups in 1980/81 [15–18]. Although the ESR spectrum of '*n*-C₈H₁₈^{•+}' provided little specific information about its structure and the latter might be considered a 'special case', the time was ripe for systematic investigation of electron transfer from alkanes. Thus, when Iwasaki and co-workers reported clear information on the structure of ethane radical cation, the study of alkane radical cations became a significant area of scientific investigation [19].

2.2.2 Electron Spin Resonance

Among the techniques available for the study of free radicals or radical ions in solution, electron spin resonance (ESR) stands out as a technique with sufficient

resolution to provide detailed information about the identity of the intermediate in question. In an external magnetic field the unpaired electron of such a species can adopt either of two spin orientations, parallel or antiparallel to the field H_0 . The two orientations are of slightly different energies. Transitions between the corresponding spin levels can be stimulated by applying radiation of a frequency satisfying the resonance condition:

$$h\nu = g\mu H_0 \quad (6)$$

where h is the Planck constant, g is a parameter characteristic for the radical under scrutiny, μ is the Bohr magneton, and H_0 is the applied magnetic field strength [20, 21].

Experimentally, resonance is approached by sweeping the field in the range near 3400 G while holding the frequency constant, typically at ca 9.6 GHz. A key contribution to the identification of the radical (ion) is due to the interaction of the unpaired spin with nearby magnetic nuclei, the so called hyperfine interaction. This gives rise to a pattern of signals characteristic for the radical (ion). The spacing of the signals and their relative intensities identify the magnitude of the interaction between the electron and a group of equivalent nuclei as well as the nuclei so coupled; these results reveal the spin-density distribution in the paramagnetic intermediate under study [20, 21].

The hyperfine coupling constants of magnetic nuclei in organic radicals range from essentially 0 to 200 G (0 to 20 mT). The resulting spectra appear in absorption with intensities determined by the Boltzmann population of the states at thermal equilibrium. This feature limits the sensitivity of the ESR method and has restricted its application to relatively stable species with lifetimes greater than a few milliseconds. Another limitation has its origin in the tendency of free radicals to dimerize, thereby annihilating the unpaired spins. Nevertheless, this method has been the method of choice for the study of numerous families of radicals and radical ions; it has proved invaluable for probing their spin-density distributions and has provided detailed insights into many structures.

Appropriate modification of the ESR spectrometer and generation of free radicals by flash photolysis enables time-resolved (TR) ESR spectroscopy [22]. Spectra observed under these conditions are remarkable for their signal directions and intensities. They can be enhanced as much as one-hundredfold and appear as absorption, emission, or a combination of both. Effects of this type are a result of chemically induced dynamic electron polarization (CIDEP); these spectra indicate the intermediacy of radicals whose sublevel populations deviate substantially from equilibrium populations. Significantly, the splitting pattern characteristic of the spin-density distribution of the intermediate remains unaffected; thus, the CIDEP enhancement not only facilitates the detection of short-lived radicals at low concentrations, but also aids their identification. Time-resolved ESR techniques cannot be expected to be of much use for electron-transfer reactions from alkanes, because their oxidation potentials are prohibitively high. Even branched alkanes have oxidation potentials well above the excited-state reduction potential of typical photo-

Figure 1. (a, left) Preferred configuration of electron spins in the σ orbital connecting a ^1H nucleus to an sp^2 -hybridized C atom bearing unpaired π spin density (π, σ -polarization); (b, center) “molecular π orbital” consisting of two carbon p_z orbitals and an H_2 “group orbital” due to hyperconjugation between an sp^2 -hybridized C atom bearing unpaired spin and a $\text{CH}_2\text{-R}$ group (π, σ -delocalization); (c, right) delocalization of an unpaired electron throughout the C–C σ -frame and extending directly into two chain-end in-plane C–H bonds (σ -delocalization).

sensitizers (see Section 2.3.3). They have, however, proved useful for some strained ring compounds (below).

The ^1H hyperfine coupling constants are related to carbon spin densities by different mechanisms of interaction. For π radicals, there are two principal mechanisms involving either induction (π, σ -polarization) or delocalization (π, σ -delocalization, hyperconjugation). Protons attached directly to carbon atoms bearing positive spin-density have negative hyperfine coupling constants because of the preferred exchange interaction between the unpaired π spin-density and the carbon σ electron (Figure 1a). Positive hyperfine coupling constants, on the other hand, are usually observed for protons which are one C–C bond removed from a carbon bearing positive spin-density. The positive sign is a result of a hyperconjugative interaction which delocalizes the π spin-density on carbon into an H_n ‘group-orbital’ (cf. Figure 1b). Finally, the radical cations formed upon electron transfer from n -alkanes are typically σ radicals, in which the unpaired electron is delocalized throughout the carbon framework and extends directly into the two chain-end in-plane C–H bonds, resulting in large positive hyperfine coupling constants for these ^1H nuclei (Figure 1c).

In the next section we discuss the radical cations generated upon electron transfer from simple n -alkanes to holes generated in various matrices upon radiolysis. The ESR spectra observed in these matrices reveal many interesting structural details. We will begin with the special case of the long-elusive methane radical cation, followed by the radical cations of n -alkanes and those of branched alkanes.

2.2.3 Electron-transfer Reactions of Methane

Electron transfer from methane is significant because it seems likely that $\text{CH}_4^{\bullet+}$ and secondary intermediates derived from it (CH_3^\bullet , CH_3^+) played a significant role in

Figure 2. Possible Jahn-Teller distorted geometries for methane radical cation.

the chemical evolution preceding the origins of life. Methane is a likely constituent of early planetary atmospheres and its radical cation has potential significance as an interstellar species [23]. In the laboratory, however, the ESR spectrum of this species has long been elusive, probably because methane is the alkane most difficult to oxidize and its radical cation is least stable. For example, radiolysis experiments in SF_6 only gave complexes of methyl radical with a fluorinated compound [24]. In 1984, Knight and co-workers succeeded in the ESR detection of $\text{CH}_4^{+\bullet}$ in a neon matrix at 4 K [25]. Neon discharge ionization of methane ($IP = 12.6$ eV) gave rise to a quintet ($a_{\text{H}} = 5.48$ mT) whereas methane- D_2 gave rise to a 1:2:1 triplet ($a_{\text{H}} = 12.17$ mT) of 1:2:3:2:1 quintets ($a_{\text{D}} = 0.222$ mT). The a_{D} splitting corresponds to an a_{H} splitting of 1.4 mT.

For a species with tetrahedral symmetry (T_d), Jahn–Teller distortion upon ionization can lead to radical cations of C_{3v} , C_{2v} , or D_{2d} symmetry (Figure 2). The ESR spectrum observed for $\text{CH}_4^{+\bullet}$ suggests the presence of four equivalent protons, i.e., a species with D_{2d} symmetry. On the other hand, the spectrum of $\text{CH}_2\text{D}_2^{+\bullet}$ clearly shows the presence of two non-equivalent pairs, i.e., a species with C_{2v} symmetry. C_{2v} symmetry was, therefore, assigned to both $\text{CH}_4^{+\bullet}$ and $\text{CH}_2\text{D}_2^{+\bullet}$; the perprotio species, $\text{CH}_4^{+\bullet}$, is assumed to undergo dynamic Jahn–Teller distortion (fluxional behavior), so that the spectrum reflects an averaged geometry. The 5.48 mT splitting of $\text{CH}_4^{+\bullet}$ is essentially equal to the average splitting of the C_{2v} species, $[a_{\text{H}} + (a_{\text{D}} \times 6.5)]/2 = (12.17 - 1.46)/2 = 5.36$ [25].

Ab initio calculations on $\text{CH}_4^{+\bullet}$ at the UHF/6-31G* level indicated the presence of two elongated (116.4 pm) and two shortened (107.5 pm) C–H bonds with hyperfine coupling constants, $a_{\text{H}} = 13.7$ mT and $a_{\text{H}} = -1.7$ mT, respectively. For $\text{CH}_2\text{D}_2^{+\bullet}$, the deuterons preferentially occupy the shorter bonds [25]. The C_{2v} symmetry assigned to $\text{CH}_4^{+\bullet}$ is the same as that of BH_4^+ [26, 27], with which it is isoelectronic. The radical cation of C_{2v} symmetry (two different types of C–H bond) was probed by Eriksson and collaborators by a wide range of different calculation methods; the results are summarized in Table 1 [28]. The nature of the (large amplitude) tunneling among Jahn–Teller distorted structures was elucidated in a group theoretical study [29] and by results obtained with various isotopomers [30].

It is noteworthy, that ab initio calculations even for small molecules give substantially different results depending on the basis set and the method used to take electron correlation into account. These difficulties are illustrated here with the results from three different calculations on two different methane radical cations. At

different levels of theory the relative energies of the different SOMOs change along with the structure parameters. Accordingly, the global minimum can depend on the method of calculation and more than one species might become local minima. For the methane radical cation calculations with the 6-31G* basis set at different levels of electron correlation gave considerably different results. At the UHF/6-31G* level, a C_s species reported earlier [25] was the global minimum, whereas the D_{2d} structure had one negative frequency. Using UB3LYP/6-31G*, the D_{2d} structure was the global minimum, whereas the C_s structure showed one negative frequency. Finally, the UMP2/6-31G* level gave both D_{2d} and C_s species as minima with similar energies, but different hyperfine coupling patterns (Table 1; Figure 3) [31]. The ^1H nuclei connected by long bonds have strong positive hyperfine coupling constants. Aside from the different ^1H hyperfine coupling patterns (which might be masked in the experiment by dynamic Jahn–Teller effect) the two structures have significantly different isotropic ^{13}C hyperfine couplings. The D_{2d} structure has a very small ^{13}C hyperfine coupling (−0.36 to 0.42 mT), whereas the C_s species has a more significant interaction (1.8–3.3 mT) [31]. Accordingly, the actual structure should be identified unambiguously by the isotropic ^{13}C hyperfine splitting. Unfortunately, the spectra of $^{13}\text{CH}_4^{+\bullet}$ are anisotropic, and the isotropic coupling is not known unambiguously [30].

2.2.4 Electron-transfer Reactions of *n*-Alkanes

The ESR spectrum of ethane radical cation at 4 K in SF_6 contained a 1:2:1 triplet because of two strongly coupled protons (15.25 mT), corresponding to a spin-

**Figure 3.** Possible Jahn-Teller distorted geometries for methane radical cation.

Figure 4. Schematic representation of the SOMO for ethane radical cation.

density of 0.3 in the H_{1s} orbital. The hyperfine coupling of the remaining four protons is smaller than the linewidth (≤ 1 mT) [19]. The coupling documents an unambiguous example of σ -delocalization. Another important result is the direct detection of static Jahn–Teller distortion. These effects are usually based on indirect detection, i.e., via the temperature-dependence or isotope effects on hyperfine coupling [32–34]. In a few special cases, the distortion is believed to be introduced by the matrix [35, 36]. However, for most alkane radical cations (with the notable exception of $C_3H_8^{*+}$, *vide infra*), the coordinate of distortion is independent of the matrix; the mode of distortion appears to be intrinsic to the radical cations. The matrix only serves to stabilize the distorted form [37].

These results suggest that the C_2H_6 molecule (D_{3d} symmetry) is distorted to D_{3d} symmetry in the electron-transfer process generating $C_2H_6^{*+}$. The mode of deformation was associated with a Jahn–Teller active rocking vibration (e_g) of the methyl groups (Figure 4) [38]. The structure of the resulting radical cation resembles diborane, B_2H_6 , rather than the diborane anion, $B_2H_6^-$, with which it is isoelectronic [39].

Upon raising the temperature to 77 K, the spectrum changes to a septet with a splitting of 5.04 mT, one third of the value at 4 K. This change was ascribed to a dynamic Jahn–Teller effect, viz., rapid equilibration of three equivalent distorted forms, each with two strongly coupled 1H nuclei. An apparent activation energy, $E_a = 250$ cal mol $^{-1}$, was derived for the exchange; this value is one order of magnitude smaller than that for methyl rotation in the gas phase ($E_a = 2.8$ kcal mol $^{-1}$) [19].

Detailed calculations using *ab initio* or density functional theory methods revealed two different structures for $C_2H_6^{*+}$, a ‘diborane-type’ structure and a ‘long-bond’ structure. In the diborane structure, the unpaired electron is delocalized between the C–C bond and two ‘bridging’ C–H bonds; whereas in the long-bond structure it resides principally in the C–C bond. The large positive hyperfine coupling constant observed at low temperatures [19] is reproduced well by the results of B3LYP calculations on the diborane structure [40].

The next higher homolog, propane, C_3H_8 , poses an additional interesting problem. Electron transfer from C_3H_8 gave rise to three different radical cations, depending on the matrix [41]. Different structures obtained in different matrices are ascribed to the fact that the energies of several high-lying orbitals are very close to each other. Therefore, even small perturbations as a result of the matrix can alter the relative energies of these levels.

Figure 5. Schematic representation of three SOMOs corresponding to three different propane radical cations observed by ESR.

The species observed in F113 has two strong hyperfine interactions (10.5 mT) and four weaker ones (5.25 mT). This spectrum was assigned to a delocalized $\text{C}_3\text{H}_8^{+\bullet}$ species with a pseudo π orbital, resulting from the antibonding combination of three pseudo π - CH_2 orbitals. The ^1H nuclei of the center carbon are most strongly coupled whereas the two protons in the C–C–C plane have negligible hfcs. The magnitude of the strong hfcs (C-2) relative to the weaker ones (C-1,3) reflects the orbital coefficient at the corresponding carbons (Figure 5) [41].

Electron transfer from C_3H_8 in SF_6 generated a different ESR spectrum—a 1:2:1 triplet with two strongly coupled protons (9.8 mT). This spectrum is compatible with a SOMO consisting of two C–H orbitals, lying in the plane of two C–C σ -orbitals. The two in-plane ^1H nuclei at C-1 and C-3 are strongly coupled [42]; the hyperfine interactions of the remaining protons were derived from line-shape analysis at higher temperatures. The out-of-plane ^1H nuclei at C-1 and C-3 have a splitting constant, $a = -0.3$ mT, whereas those at C-2 are coupled less strongly. Compared with the parent, C_3H_8 , the probable structure of the radical cation is one in which the rotational axes of the CH_3 groups are bent toward the central carbon and the two in-plane C–H bonds are lengthened (4b_1 symmetry).

A third structure type of $\text{C}_3\text{H}_8^{+\bullet}$ was obtained in C_3F_8 ; the ESR spectrum of this species has only one strongly coupled ($a = 8.4$ mT) and one moderately coupled proton ($a = 1.8$ mT); the other splittings are considerably weaker ($a = 0.9, 0.6$ mT). Deuteration at C-2 identified the 0.6 mT splitting as due to the protons at C-2. The spectrum was assigned to a radical cation with one lengthened C–C bond. The two major splittings were assigned to the in-plane terminal protons at the lengthened bond and at the shorter one, respectively [43, 44].

Eriksson and colleagues used the 4b_1 species as a test case for a wide range of different calculation methods (Figure 5; Table 2) [28]. More recent detailed calculations revealed two different minima on the $\text{C}_3\text{H}_8^{+\bullet}$ potential surface, corresponding to the structure types with either two or one lengthened C–C bonds (Table 2).

^a According to [28].

Electron-transfer reactions of the longer *n*-alkanes generated the higher homologs of the σ -delocalized radical cation, C₃H₈^{•+} observed in F113. The resulting radical cations also have 1:2:1 ESR triplets with two strongly coupled protons [41, 45–47]. The splitting decreases sharply from 5.5 mT for C₄H₁₀^{•+} to 1.0 mT for C₁₀H₂₂^{•+}. By analogy to the C₃H₈^{•+} structure in F113, the SOMOs are σ -orbitals spread over fully extended planar C–C systems; two C–H group-orbitals at the terminal carbons contain the strongly coupled ¹H nuclei (Figure 6). The steadily diminishing hfcs with increasing chain length can be attributed to the distribution of the unpaired electron spin over an ever-increasing number of carbons (Figure 7). The hyperfine coupling constants of the inner protons and the out-of-plane methyl protons are typically small and are resolved only in special cases [42, 48].

Actually, the ESR spectra are more complex than the above simple description based on the exclusive formation of fully extended radical cations. In most frozen matrices, depending on the chain length, radical cations in *gauche* conformations were also detected [41, 49–53]. In the *gauche* forms, the spin delocalization is ter-

**Figure 6.** Schematic representation of the SOMOs for butane through hexane radical cations.

Figure 7. Hyperfine coupling constants (mT) of the in-plane chain-end ^1H nuclei for extended σ radical cations of ethane through heptane.

minated at the *gauche* carbon and the unpaired electron is confined mostly to the longer fragment. Therefore, the hfc's of the in-plane ^1H nuclei become larger than for the fully extended conformers. The strongly coupled protons are one chain-end ^1H nucleus and an additional in-plane ^1H nucleus at the *gauche* carbon; the latter has a slightly larger hfc because the *gauche* carbon has slightly greater spin-density [41, 50]. The co-existence of two conformers is illustrated for *n*-pentane, which can exist in the *s-trans,trans,trans*- and the *s-trans,trans,gauche*-conformation (Figure 8). The observed ESR spectrum was dissected into two independent contributions, a

Figure 8. Schematic representation of the SOMOs for two conformers of pentane radical cation.

narrower one for the linear conformer and a spectrum with wider extension for the kinked one. The different spin and charge densities at the chain-end and the *gauche* carbon causes the ^1H nuclei attached 'in-plane' to have different reactivities (see Section 2.2.5).

An interesting extension of these results was observed upon radiolysis inside pentasil zeolite (ZSM-5) [54]. The oxidation potentials of alkanes are too high to enable oxidation by the zeolite; indeed, incorporation of alkanes into Na- or HZSM-5 does not give rise to any absorption above 260 nm (cf. Section 2.2.6). Therefore, the neutral hydrocarbon molecules undergo electron transfer to holes generated in the zeolite upon radiolysis. At low alkane concentration (loading 0.5 % by weight), only the characteristic triplets of the extended radical cations, ($n = 3,5$), were observed (*n*-hexane, $a = 3.9$ mT; *n*-octane, $a = 2.9$ mT). Comparison of these spectra with those obtained in SF_6 and chlorofluorocarbons [19] revealed that only the fully extended conformers of the alkane radical cations are present in the zeolite enforced by the geometry of the zeolite channels [19].

Radiolysis at higher substrate loadings (3.0 % by weight), yielded different spectra, which were assigned to the corresponding primary alkyl radicals, ($n = 3,5$). Because the appearance of the new species was concentration-dependent, their formation was ascribed to an ion-molecule reaction, generating a protonated *n*-alkane, at the same time [54].

2.2.5 Deprotonation of *n*-Alkane Radical Cations

The reaction of the *n*-hexane and *n*-octane radical cations with their diamagnetic parents to generate alkyl radicals and protonated *n*-alkanes is one of the few reactions observed for *n*-alkane radical cations. Under the limited range of conditions in which they can be generated, only a limited range of reagents is available. The bimolecular H-atom transfer seems to be a general reaction for *n*-alkane radical cations. This reaction is not limited to zeolite media but occurs in halogen-containing matrices also. The mechanism of these conversions poses several interesting questions. The key step can involve transfer of a proton to the neutral *n*-alkane (Eq. 7) or abstraction of hydrogen atom from the *n*-alkane (Eq. 8). Additional questions concern the donor site, from which H^{\cdot} or H^+ originate, and the acceptor site to which H^{\cdot} or H^+ is transferred. The mechanism of this conversion was elucidated by Ceulemans and coworkers in elegant studies of *n*-heptane and *n*-octane in CCl_3F [55, 56].

The prevailing conformers of alkane radical cations depend on specific interactions between the host matrix and the guest alkane. For example, γ -irradiation of *n*-heptane in CCl_3F generated an extended all-*trans* conformer of $n\text{-C}_7\text{H}_{16}^{*+}$, whereas *n*-octane gave rise to the *gauche* at-C2 conformer of $n\text{-C}_8\text{H}_{18}^{*+}$. In experiments with $n\text{-C}_7\text{H}_{16}$ containing small amounts of $n\text{-C}_8\text{D}_{18}$, the spectrum of 1-heptyl radical, $n\text{-C}_7\text{H}_{15}\cdot$, was superimposed on that of $n\text{-C}_7\text{H}_{16}^{*+}$; this finding was ascribed to H^+ transfer from $n\text{-C}_7\text{H}_{16}^{*+}$ to $n\text{-C}_8\text{D}_{18}$. The preferential formation of primary heptyl radical during the early phase of the reaction identified a chain-end carbon as the donor site. This conclusion is in agreement with the reactivity expected for a σ -delocalized radical cation; a proton of a lengthened and weakened C–H bond should be donated preferentially. This is the same proton which also has a strong hyperfine coupling constant. The formation of secondary heptyl radicals appearing at higher *n*-heptane concentrations was explained as a result of intermolecular radical site transfer.

Analogous experiments with *n*-octane revealed that the secondary octyl radical, $2\text{-C}_8\text{H}_{17}\cdot$, was present from the very onset of proton transfer, suggesting the 2-position as the donor site. γ -Irradiation of *n*-octane generates the *gauche* at-C2 conformer of $n\text{-C}_8\text{H}_{18}^{*+}$, a species with large unpaired electron density on one in-plane chain-end C–H bond and on the in-plane C–H bond at C2 [55]. The formation of secondary octyl radical clearly supports significant donor site selectivity for H^+ transfer from *n*-alkane radical cations to *n*-alkanes. The *gauche* at-C2 conformer of $\text{C}_8\text{H}_{18}^{*+}$ reacted at the site of greater electron spin (and positive hole) density (C2) and generated the more stable free radical. Thus, this mode of reaction is favored by both kinetic and thermodynamic principles.

Deprotonation from the carbon of highest spin-density has been suggested as a general rule. This is strongly supported by the deprotonation of the propane radical cation in different matrices. The $\text{C}_3\text{H}_8^{*+}$ species observed in F113, which has high spin-density on C-2 (Figure 5) and strongly coupled secondary protons (10.5 mT) gave rise to 2-propyl radical. In contrast, the $\text{C}_3\text{H}_8^{*+}$ species formed in SF_6 , which has high spin-density on C-1 and C-3 and in which the chain-end in-plane ^1H nuclei are strongly coupled, generated the 1-propyl radical [41]. Additional strong evidence for this principle was derived from the deprotonation of isobutane radical cation (Section 2.2.6). On the other hand, it has been noted that the spin-density–reactivity correlation might not hold universally [41, 46, 49, 51].

The H^+ acceptor site was identified by experiments on $n\text{-C}_7\text{H}_{16}$ containing different amounts of $n\text{-C}_8\text{D}_{18}$ and a small percentage of 1-chlorohexane (e.g. Eq. 9). These experiments revealed the formation of small amounts of chlorooctanes, presumably via neutralization of protonated octane molecules by chloride ions. Among

the resulting chlorooctanes, the 2-isomer predominates, identifying C2 as the primary H^+ acceptor site [55].

2.2.6 Electron-transfer Reactions of Branched Alkanes

Branched alkanes are somewhat more easily oxidized than *n*-alkanes, although typically still quite unreactive. Their ionization potentials are barely lower than those of *n*-alkanes, ranging from 10.68 eV for 2-methylpropane to 9.89 eV for 2,2,4-trimethylpentane. As typical saturated hydrocarbons they are unreactive in the potential range that is experimentally accessible in non-aqueous solvents. Some branched alkanes with especially weak C–H bonds can, however, be oxidized under these conditions. For example, oxidation potentials (relative to the Ag/Ag^+ electrode) were assigned to 2,2-dimethylbutane (ca 3.3 V) or 2-methylpentane (ca 3.0 V) [57]. The radical cations of branched alkanes have interesting structural features. Electron transfer from the simplest branched alkane, 2-methylpropane, to electron holes generated in a halocarbon or SF_6 matrix gave rise to two different radical cations, of C_s and C_{3v} symmetry. Radiolysis in SF_6 at 4 K generated a radical cation, whose ESR spectrum contained a triplet ($a_H = 5.8$ mT). In this radical cation the unpaired spin is localized largely in one C–C bond (C_s symmetry); two *trans*- β -protons, one on each adjacent methyl group, are strongly coupled [19, 41]. This species is deprotonated to form *iso*-butyl free radical by loss of H^+ from a methyl group. Radiolysis in Freon at 4 K generated the same C_s radical cation. However, warming to 77 K caused irreversible conversion to a different species (C_{3v} symmetry), in which the spin is localized largely in the tertiary C–H bond, causing the tertiary proton to be strongly coupled ($a_H = 25.0$ mT) (Figure 9) [41]. This species is deprotonated to form *t*-butyl free radical.

It was the oxidation of 2,2,3,3-tetramethylbutane (hexamethylethane), studied independently in three different laboratories, which might have signaled the onset of systematic investigation of electron-transfer reactions from alkanes and of the structures of the resulting radical cations. Oxidation of hexamethylethane generated a radical cation with a seven-line ESR spectrum with $a_H = 2.9$ mT. The unpaired spin of this radical cation is localized in the central C–C bond; six *trans*- β -protons, one on each adjacent methyl group, are strongly coupled by hyperconjugation [17]. The hyperfine couplings of the *gauche* β -hydrogens were also assigned ($a_H =$

Figure 9. Schematic representation of σ - and π -SOMOs considered for isobutane radical cation.

Figure 10. Schematic representation of SOMOs for *s-trans,trans*-2-methylbutane and *s-trans,trans*-3-methylpentane radical cations.

0.42 mT) [18]. Interestingly, the six methyl groups remain static even at 77 K [18] in considerable contrast to the facile rotation of the methyl groups of the ethane radical cation. The reason for the pronounced hindrance of methyl rotation must lie in the significant steric congestion of the tetramethylbutane framework.

Electron transfer from 2-methylbutane [58] and 3-methylpentane [58, 59] generated remarkably similar ESR spectra—both donors gave rise to four-line spectra with $a_H \approx 4.5$ mT. These patterns were rationalized in terms of radical cations, with the unpaired spin localized in the C3–C4 bond; the large hfcs arise from one proton in each of three methyl groups (Figure 10) [58, 59]. Radiolysis of specific deuterated derivatives and spectral simulations led Shiotani and coworkers to a refined assignment [58]. Details go beyond the scope of this review.

Many other branched alkanes undergo electron-transfer reactions in cryogenic matrices. Although the ESR spectra of the resulting radical cations reveal interesting structural features [60–62], detailed discussion would exceed the scope of this review.

2.2.7 Electron Transfer from Alkanes to Zeolites

Zeolites were introduced as catalysts for large-scale heterogeneous reactions in petrochemistry, because they have significant advantages for processes such as cracking, aromatic isomerization, or disproportionation [63–68]. One of the most intriguing properties of acid zeolites is their spontaneous generation of organic radical cations on adsorption of organic electron donors [69]. Molecules containing strained rings are especially readily converted to their radical cations on incorporation into zeolites [70], although radical cations have also been obtained from selected alkanes. Because radical cations sequestered in zeolite pores are protected from reagents that typically would cause their decay in solution, their lifetimes are increased so that they can be studied by conventional spectroscopic techniques. Also, the limiting geometry of the zeolite pores can manifest itself in two ways: (i) it might selectively incorporate substrates with suitable geometries (shape selectivity); and (ii) it might restrict the geometry (conformation) of a sequestered intermediate. Thus, *trans*-1,2-diphenylcyclopropane was incorporated readily into ZSM-5 where-

as the *cis* isomer was not [70]. On the other hand, radiolysis of *n*-hexane and *n*-octane in pentasil zeolite generated solely the EPR spectra of the 'extended' radical cations (*vide supra*) [54].

Radical cations are also generated efficiently upon γ -radiolysis of appropriate 'guests' sequestered in zeolites. In this experiment, a 'hole' and a free electron are generated in the zeolite, and the guest transfers an electron to the 'hole'. Given the redox- and acid-base-active nature of zeolites it is not obvious whether the original substrate or a rearranged product is oxidized by interaction with the newly created 'hole'. In fact, many alkenes undergo significant reactions before the onset of radiolysis.

Chen and Fripiat succeeded in generating radical ions from saturated hydrocarbons, e.g., 3-methylpentane (**1**), upon sequestering them into H-mordenite and heating for several hours [71]. The resulting species were identified by their EPR spectra [72]. Adsorption of **1** and heating to 100 °C for 4 h produced a 'nine-line spectrum' ($a = 17.3$ G, $g = 2.003$), which was identified by Roduner and Crockett as that of the 2,3-dimethylbutene radical cation (**2** $^{+\bullet}$) [72]. Although an electron-transfer step must be involved at some stage of this conversion, it is not clear at what stage electron transfer to the zeolite occurs.

Significant applications of γ -radiolysis in the study of electron-transfer processes and radical cations in zeolites have emanated from the radiation group at Argonne National Laboratories [73]. For example, Barnabas et al. studied the fate of highly branched alkanes, 2,3-dimethylbutane, 2,2,3-trimethylbutane, and 2,2,3,3-tetramethylbutane, upon γ -radiolysis in pentasil zeolite (ZSM-5) [74, 75].

γ -Radiolysis of 2,3-dimethylbutane (**3**) in pentasil zeolite at 4 K forms the corresponding radical cation (**3** $^{+\bullet}$; a broad quintet, $a = 3.7$ mT); by analogy with typical radical cations of branched hydrocarbons, the quintet is caused by coupling of a single proton per methyl group. In addition, 2,3-dimethyl-2-butyl free radical (**4** $^\bullet$), recognized as a septet ($a = 2.34$ mT) of doublets ($a = 0.55$ mT), is formed to a lesser extent [75].

Radiolysis of ZSM-5 containing 2,2,3-trimethylbutane (**5**) at 77 K yielded a six-line spectrum characteristic of **5** $^{+\bullet}$ ($a = 3.1$ mT, 5H) [76]. Upon raising the temperature, in the range 120–200 K, the well known 2,3-dimethyl-2-butene radical

cation (2^{++}) was observed ($a = 1.7$ mT, nine lines observed, 12H). Its formation was ascribed to “thermal elimination of methane”, a reaction similar to the above-mentioned elimination of H_2 [72].

Above 200 K, an additional seven-line pattern ($a = 2.25$ mT, 6H) appeared, which was ascribed to 2,3,3-trimethyl-2-butyl radical, 6^{\bullet} , apparently as a result of deprotonation of 5^{++} . Because the abundance of this species increased with substrate loading, its formation was ascribed to an ion–molecule reaction (Section 2.2.5).

γ -Radiolysis of tetramethylbutane (7) in pentasil zeolite gave rise to a ‘seven-line’ spectrum ($a = 3.1$ mT, 6H; outer lines not distinct), identified as that of 7^{++} [72, 74]. The splitting is, once again, caused by a single (in-plane) proton per methyl group. An additional weak quartet ($a = 2.2$ mT) indicated formation of methyl radical, most probably formed by fragmentation of 7^{++} . Upon annealing at 125 K, a new spectrum appeared ($a = 1.49$ mT, 2H; $a = 1.38$ mT, 2H; $a = 0.33$ mT, 3H); this was assigned to 2-methylpropenyl free radical, 7^{\bullet} . This species was explained by rapid deprotonation of 2-methylallyl radical cation (8^{++} , not observed). This reaction, assigned by the authors to “scission of the central C–C bond” of 9^{++} [74], amounts to ‘elimination’ of 2-methylpropane (C_4H_{10}), similar to the loss of CH_4 [76] and H_2 [72] mentioned above.

Among the various conversions discussed in this section, deprotonation is clearly a general reaction of alkane radical cations. The interesting elimination or fragmentation reactions, on the other hand, seem to be zeolite-specific reactions without precedent in halogen containing matrices.

2.3 Electron-transfer Reactions of Cycloalkanes

Similar to alkanes most cycloalkanes also are quite unreactive and have very high pK_a values and low electron affinities, making them poor electron acceptors. Although the molecular anions of cycloalkanes are very unstable, temporary anion

states with lifetimes shorter than picoseconds have been observed. The four smallest ring systems, cyclopropane through cyclohexane have temporary anion states at 5.29, 5.80, 6.14, and 4.11 eV [1]. The ionization potentials of cycloalkanes are somewhat lower than those of the low *n*-alkanes (the *IP* of cyclopropane through cyclooctane lie between 9.75 and 9.90 eV); they are still poor electron donors and are difficult to oxidize in solution or in solid matrices. The molecular ions are accessible in the gas phase (electron or He_x impact ionization), as documented by their mass and photoelectron spectra. Also, simple cycloalkanes and their derivatives readily undergo electron transfer to 'holes' generated upon radiolysis of halogen-containing matrices [9–11]. Some substituted cyclopropanes and cyclobutanes undergo photo-induced electron transfer to photo-excited electron acceptors in solution, generating radical cation–radical anion pairs (Section 2.3.3).

The basic cycloalkanes with three to eight carbons (*c*-C₃H₆–*c*-C₈H₁₆) undergo electron transfer upon radiolysis in halogen-containing matrices, generating the radical cations (*c*-C₃H₆^{•+}–*c*-C₈H₁₆^{•+}). The ESR spectra observed in these systems reveal interesting structural details. Some properties of these species are discussed below. Common features include delocalization of the unpaired electron throughout the molecular frame and a noticeable positive *g*-shift relative to alkane and aromatic radical cations. In addition, the overall width of the ESR spectra, i.e., the sum of all hyperfine coupling constants, increases with increasing ring size (Figure 11). In marked contrast, a steady decrease in spectral width with increasing chain length is observed for aliphatic radical cations (cf., Figure 7). For the typical σ -delocalized linear aliphatic radical cations, only C–H bonds in the molecular plane contribute to delocalizing the unpaired electron spin. Only the in-plane ¹H nuclei are strongly coupled; typically, two terminal protons satisfy this requirement. Because the spin-density in the terminal C–H bond decreases with increasing numbers of carbons delocalizing the electron spin, so does the magnitude of the ¹H hyperfine coupling.

Among the simple cycloalkanes, we first discuss electron transfer from the three- to eight-membered cycloalkane prototypes to electron holes generated by radiolysis in different matrices, giving rise to the simple cycloalkane radical cations. Because of the significant interest they have attracted, the electron-transfer reactions of cyclopropane and, to a lesser extent, cyclobutane derivatives will be treated separately. Finally, electron transfer from some bicyclic hydrocarbons and the resulting radical cations will be discussed in a separate section (Section 2.4).

2.3.1 Electron Transfer from C₃–C₈ Prototype Cycloalkanes

Several of the simple cycloalkane radical cations, generated by electron transfer, are Jahn–Teller active. Apart from the interesting small-ring radical cations, *c*-C₃H₆^{•+} and *c*-C₄H₈^{•+}, one common-ring radical cation, *c*-C₆H₁₂^{•+}, and one medium-ring species, *c*-C₈H₁₆^{•+}, also show this interesting phenomenon. On the other hand, *c*-C₅H₁₀^{•+} and *c*-C₇H₁₄^{•+} seem to be Jahn–Teller inactive.

Cyclopropane, the simplest strained ring system, continues to be subject to intense and detailed scrutiny by a variety of techniques. Its photoelectron spectrum,

Figure 11. Sum of all hyperfine coupling constants (mT) for radical cations of C₃–C₈ cycloalkanes; the strained rings (C₃, C₄) clearly deviate from the trend of C₅–C₈.

investigated over thirty years ago, showed Gaussian shaped bands without fine structure. Molecular-orbital calculations suggest that the first two bands, a double peak centered near 11 eV, be assigned to a $^2E'$ state. The large splitting of these bands (0.8 eV), also observed for many derivatives, is ascribed to Jahn–Teller distortion of the ionic ground state [77]. The two states resulting from the distortion, 2B_2 and 2A_1 , (C_{2v} symmetry) correspond to two different molecular structures (Figure 12). In rigid matrices, cyclopropane readily undergoes electron transfer upon γ -radiolysis at 4.2 K; the ESR spectrum of the resulting radical cation has two strongly coupled ^1H nuclei ($a_{\text{H}} = 2.04$ mT) and four less strongly coupled nuclei ($a_{\text{H}} = -1.17$ mT). These splittings were assigned to the β - and α -protons, respectively, of a trimethylene (2A_1)-type radical cation structure, an equilibrium structure with one lengthened C–C bond, because of static Jahn–Teller distortion of the cyclopropane ring (D_{3h} symmetry) [78, 79]. At higher temperatures, an averaged spectrum, consisting of only a single line (FWHH = 1.5 mT), was observed. This spectrum was ascribed to an averaged structure resulting from dynamic Jahn–Teller distortion, interconverting three equivalent 2A_1 structures with three equivalent 2B_2

Figure 12. The degenerate pair of cyclopropane HOMOs, *S* and *A*, and schematic radical cation structures, *A* and *B*, resulting from removing an electron from one of the orbitals.

structures as transition states [37, 78–80]. The magnitude of a_β (2.04 mT) and a_α (–1.17 mT) fortuitously averages to $a_{\text{avg}} \approx 0$ [80].

The structure of the cyclobutane radical cation also is of major interest. The parent cyclobutane system is known to have a puckered ring with D_{2d} symmetry [81]. Electron transfer from one of the cyclobutane e orbitals is expected to lead to a Jahn–Teller unstable radical cation, which might distort to structures of D_{2d} and C_{2v} symmetry [81]. Ushida et al. studied the EPR spectra obtained upon X-irradiation of cyclobutane in frozen CFCl_3 solution [82]. At 4 K, a triplet of triplets appeared with hyperfine coupling constants, $a_{\text{H1}} = 4.9$ mT (2H), $a_{\text{H2}} = 1.4$ mT (2 H), and four weakly coupled protons ($a_{\text{H1}} = 0.5$ mT), suggesting an intermediate with C_{2v} symmetry. These findings were interpreted in terms of a radical cation that had undergone static Jahn–Teller distortion to a rhombic structure of C_{2v} symmetry (Figure 13, type D) [82]. Upon annealing the sample at 77 K, the spectrum changed irreversibly to a five-line pattern (measured at 4 K). This result was ascribed to an irreversibly reduced barrier to ring puckering and/or flattening. Finally, at temperatures above 77 K, a nearly isotropic nine-line spectrum with a hyperfine coupling constant, $a_{\text{H}} = 1.33$ mT was observed. This change was ascribed to a dynamic Jahn–Teller effect via pseudorotation. Additional structure types can be envisaged that are compatible with the low-temperature ESR pattern and cannot be rigorously eliminated [82].

The cyclobutane radical cation was calculated by several groups, who evaluated Jahn–Teller distorted structures potentially arising upon ionization of cyclobutane [79, 83–87]. Four distorted local minima were considered (Figure 13). A rectangular structure with two weakened C–C bonds (type A) and a rhomboidal structure with four weakened C–C bonds (type B) result from first order Jahn–Teller distortion. Two further structures, a trapezoidal one (one weakened C–C bond; type C), and an irregular structure shaped like a kite (two lengthened C–C bonds; type D) can be envisaged as a consequence of second-order Jahn–Teller distortion [86]. A detailed recent study also considered puckered equivalents of the planar structure types, A–D

Figure 13. Possible structure types of cyclobutane radical cations.

[86]. At the QCISD-(T)/6-31G**/UMP2/6-31G* level of theory a rhombic structure, quite flexible to ring-puckering, emerged as the most stable.

The most recent study, using UHF, MP2, BLYP and B3LYP methodologies, reached somewhat different conclusions. Density functional theory calculations showed one imaginary frequency for the rhombic structure (four equivalent bonds, 157.3 pm), suggesting that it is a (very low-lying) transition structure between two parallelograms (two pairs of equivalent bonds, 149.5 and 169.5 pm, respectively) [87]. A calculation of the hyperfine coupling constants for the minimum yielded values, $a = 2.09, 0.29$ mT; the rather poor agreement with the experimental splittings, $a = 4.9, 1.4$ mT, is unsettling, particularly because hyperfine coupling constants calculated for many strained-ring systems are in significantly better agreement with experiment. Because hyperfine coupling patterns (and the related CIDNP patterns) are the only experimental data available for many strained ring systems, closer reproduction of these data by calculation seems desirable.

In contrast to the radical cations of strained-ring cycloalkanes, the cyclopentane radical cation, $c\text{-C}_5\text{H}_{10}^{+\bullet}$, formed by electron transfer to radiolysis-induced holes in halocarbon matrices, had a simpler spectrum. A triplet with $a_{\text{H}} = 2.5$ mT (2H) was attributed to a localized species with C_s symmetry. The unpaired electron was assigned to a W-shaped σ -orbital, involving C5–C1–C2, and the two equatorial protons at C5 and C2 [80, 88, 89]. At temperatures above 77 K, all ring protons become equivalent, most probably as a result of processes such as ring inversion, or pseudo-rotation around the C5-axis [89].

Five-membered rings typically have non-planar conformers, either a puckered C_2 ‘envelope’ or a C_s ‘half chair’ (Figure 14). The conformers are readily interconverted by flipping one CH_2 from above the approximate ring plane to below. Ring inversion converts the molecule into its mirror image, interchanging equatorial and

Figure 14. Conformers of cyclopentane and schematic representation of possible singly occupied molecular orbitals (SOMOs) of cyclopentane radical cation.

axial ^1H nuclei at a given carbon, whereas pseudo-rotation would move the unpaired electron spin to an adjacent set of carbon atoms. Spectra simulation led to estimates of $1.2 \text{ kcal mol}^{-1}$ for the barrier of ring inversion and $3.6 \text{ kcal mol}^{-1}$ for the barrier to pseudo-rotation [84]. The observed ESR pattern is consistent with either the C_s or the C_2 structure. Ab initio calculations carried out at the time supported a $^2A''$ state with the σ -type W shaped SOMO [80, 88]; however, an element of ambiguity persisted, because the calculations did not reproduce the radical cation well. Alternatively, the unpaired electron may be localized mainly in one C–C bond (Figure 14) interacting mainly with two quasi-equatorial β hydrogens. Recent ab initio calculations (6-31G* basis set, UHF, UB3LYP, or UMP2) favored the alternative structure. The C3–C4 bond was significantly lengthened (ca 210 pm) and the electron spin-density was almost entirely localized at C3,4 ($\rho_{3,4} = 0.46$, UB3LYP) [31]. At this level, only the quasi-equatorial ^1H nuclei had large hyperfine coupling constants ($a_{2,5} = 1.98 \text{ mT}$), although still somewhat different from the experimental values.

Interestingly, the averaged hyperfine coupling of the eleven-line spectrum changes significantly in different matrices, ranging from 0.59 mT in C_6F_{12} to 0.77 mT in CFCl_3 . This result might suggest that the electronic ground state is influenced by the nature of the matrix. Other matrix-dependent ESR spectra will be discussed for the radical cations of the bicyclo[4.4.0]decane isomers (Section 2.4.2).

Electron transfer from *c*- C_6H_{12} was studied by many groups as a convenient and simple target for pulse radiolysis [37, 90–93]. Radiolysis of *c*- C_6H_{12} in Freon-113

Figure 15. Possible SOMOs of cyclohexane radical cations. Because the a_g and b_g SOMOs are incompatible with the observed hyperfine coupling pattern, further distortion of the b_g SOMO to an a'' SOMO was suggested [94, 95].

produced a Jahn–Teller active radical cation, $c\text{-C}_6\text{H}_{12}^{+\bullet}$. The spectra observed at 4 or 77 K were broad and difficult to analyze. The ESR spectrum at 4 K contained three pairs of equivalent protons, $a_{\text{H}} = 8.5$ mT, $a_{\text{H}} = 3.4$ mT, $a_{\text{H}} = 1.4$ mT. Jahn–Teller distortion of the degenerate E_g structure (a D_{2d} chair) might lead to either a 2A_g or a 2B_g state (C_{2h} symmetry; Figure 15) [92, 93]. The observed spectrum was assigned to a radical cation of 2A_g structure, with two elongated C–C bonds and the splitting to the six equatorial protons of $c\text{-C}_6\text{H}_{12}^{+\bullet}$ [37, 92]. The simple species fitting this description would have four equivalent protons, however; an additional distortion, twisting two ${}^1\text{H}$ nuclei ‘out of plane’, must, therefore, be invoked to account for the spectrum [94, 95]. At temperatures ≥ 140 K a well resolved seven-line spectrum appeared ($a_{\text{H}} = 4.3$ mT); this is readily explained as the average of three rapidly equilibrating 2A_g structures with an estimated activation barrier between 170 and 240 cal mol $^{-1}$ [37].

Electron-transfer reactions of higher cycloalkanes were also studied. Electron transfer from $c\text{-C}_7\text{H}_{14}$ to unstable holes generated by radiolysis in Freon-113 gave rise to a stable radical cation, $c\text{-C}_7\text{H}_{14}^{+\bullet}$; its spectrum was interpreted in terms of a twisted chair form with C_2 symmetry [37]. Finally, radiolysis of $c\text{-C}_8\text{H}_{16}$ in a Freon-113 matrix generated a Jahn–Teller-active radical cation, $c\text{-C}_8\text{H}_{16}^{+\bullet}$, with three sets of non-equivalent protons [37]. A detailed discussion of these species exceeds the scope of this review.

2.3.2 Cyclopropane Radical Cations

Cyclopropane has a degenerate pair of in-plane e' orbitals (S, A). Accordingly, vertical ionization leads to a doubly degenerate ${}^2E'$ state. Jahn–Teller (JT) distor-

tion of this state results in two non-degenerate electronic states, 2A_1 and 2B_2 (C_{2v} symmetry) [96–104]. The 2A_1 component (orbital S singly occupied) relaxes to an equilibrium structure with one lengthened C–C bond, which is the lowest energy species for many cyclopropane radical cations (Figure 12). This assignment is based unambiguously on ESR [78, 105, 106] and nuclear spin polarization (CIDNP) studies (cf. below) [107–110]. The two structure-types considered for the cyclopropane radical cation, 2B_2 ('type **B**') and 2A_1 ('type **A**') pose several interesting questions. Which structure is of lower energy? Can the 2A_1 species undergo ring-opening to trimethylene radical cation? How is the ring-opened species related to propene radical cation? How do substituents affect the relative stabilities of the 2B_2 and 2A_1 structures? These questions have been pursued in theoretical and experimental studies. We will review some molecular orbital calculations and discuss them in the light of experimental results.

Molecular orbital calculations

The radical cations of cyclopropane have long been the target of theoretical investigations) [96–104]. Here, we will discuss mainly a thorough *ab initio* study by Borden and co-workers [101], dealing with the cyclopropane radical cation, 10^{*+} , its potential ring opening to trimethylene radical cation, 11^{*+} , and the further rearrangement to propene cation radical 12^{*+} . In addition, we will briefly mention a study by Krogh-Jespersen and Roth [103], dealing specifically with the existence of the 2B_2 structure type and its potential stabilization by appropriate substituents, and two papers dealing with the ring-opened species [102, 104].

In view of the significant ring-strain of the cyclopropane system, it is hardly surprising, that the propene radical cation, 12^{*+} was found to be the lowest energy isomer on the $C_3H_6^{*+}$ potential surface. At the unrestricted Hartree–Fock (UHF/6-31G*/MP2/6-31G*) level (C_s symmetry), 12^{*+} lies ca 10 kcal mol $^{-1}$ below the 2A_1 radical cation with only one lengthened C–C bond ' 10^{*+} '. A vibrational analysis of this structure showed only positive frequencies, thus identifying this species as a local minimum. In contrast, the ring-opened trimethylene radical cation, 11^{*+} , does not appear to be a minimum, because vibrational analysis in C_{2v} symmetry showed one imaginary and one low frequency.

Additional geometries in which the terminal CH₂ groups were rotated relative to the plane of the three-carbon unit from orientation '0' (in plane) to orientation '90' (perpendicular) likewise failed to qualify as local minima. The calculations failed to indicate a chemically significant barrier for the conversion of 11^{*+} to 12^{*+} . The essence of these findings was confirmed by UMP2/6-31G* calculations of Skancke [104], who identified the conversion of 10^{*+} (2A_1) to 12^{*+} as a one-step reaction with a barrier of ca 30 kcal mol⁻¹, approximately one half that measured for the parent system [111, 112]. In summary, these calculations argue against the opening of 10^{*+} to 11^{*+} reported to occur in CF₂Cl-CFCl₂ matrices, even at cryogenic temperatures [105, 106]. On the other hand, it is possible that matrix forces affect the prevailing structure. We will discuss several examples of effects of this nature (*vide infra*).

Photoinduced electron transfer of cyclopropane systems

The ring-strain inherent in cyclopropane makes it a significantly better electron donor than non-strained cyclic hydrocarbons. Accordingly, a wide range of cyclopropane derivatives undergo electron transfer upon interacting with acceptor excited states. The resulting 'photoinduced electron transfer' (PET) is a mild and versatile method for the generation of radical cation-radical anion pairs in solution (Scheme 1) [113–115]. The PET method utilizes the fact that the oxidative power of an acceptor and the reductive power of a donor are substantially enhanced by photoexcitation. Thus, donor-acceptor pairs with negligible or weak interactions in the ground state, can readily undergo electron transfer, generating radical ion pairs, if either reactant is excited electronically. For the study of radical cations it is advantageous to excite the acceptor (Eq. 10). Depending on the nature of the acceptor and its lifetime, it will be quenched before or after intersystem crossing to the triplet state.

In Scheme 1, the reaction is formulated for triplet quenching (Eq. 11), which generates radical ion pairs of triplet spin multiplicity. Even so, the resulting radical ions have limited lifetimes, because the pairs readily undergo intersystem crossing

Scheme 1.

(Eq. 12), followed by recombination of the singlet pairs (Eq. 13); alternatively, separation by diffusion (Eq. 14) might generate 'free' radical ions.

The most common triplet-state electron acceptors are ketones and quinones, whereas aromatic hydrocarbons, often bearing one or more cyano groups, are the most frequently used singlet-state electron acceptors. For the generation of radical cations from a given donor it is important that the exothermicity of electron-transfer reactions can be adjusted to fall within an appropriate range, typically between 0.2 and 1.0 eV. The change in free energy (ΔG) for an electron-transfer reaction is given by the Rehm Weller equation (Eq. 11) [116]

$$\Delta G = -E_T - E_{\text{red}} + E_{\text{ox}} - e^2/\epsilon a \quad (15)$$

where E_T is the excited state energy (0–0 transition), E_{ox} is the one-electron oxidation potential of the donor, E_{red} is the one-electron reduction potential of the acceptor, and a is the distance (Å) between donor and acceptor. The term $e^2/\epsilon a$ (Coulomb term) takes account of ion pairing. Alternatively, one can define the reduction potential of the acceptor excited state as

$$^*E_{\text{red}} = -E_T + E_{\text{red}} \quad (16)$$

The application of PET is limited to the oxidation of substrates with oxidation potentials well below the threshold value defined by $^*E_{\text{red}}$. According to Eq. 16 the change in free energy of the reaction can be tuned by variation of the solvent (polarity) and of the acceptor (reduction potential, excited-state energy). For a given class of acceptors the excited state energies typically vary over a narrow range, whereas the reduction potentials can be altered substantially by the introduction of appropriate substituents (Table 3). It is not, therefore, generally a problem to adjust the exothermicity to an appropriate range.

The parent cyclopropane system does not, in fact, readily undergo electron transfer in solution; apparently, the excited state reduction potentials of most sensitizers are too low (Table 3). However, introducing simple alkyl substituents increases the donor capacity of the cyclopropane system. This is aptly shown by the (gas-phase) ionization potential of 1,1-dimethylcyclopropane (9.0 eV) compared with that of cyclopropane (9.87 eV). PET from a series of methyl-substituted cyclopropanes to photoexcited chloranil was probed in solution. These experiments failed to provide evidence for electron transfer from *cis*- or *trans*-1,2-dimethylcyclopropane. On the other hand, 1,1,2-trimethyl- and 1,1,2,2-tetramethylcyclopropane were oxidized [108, 109].

Conjugation with one or two phenyl groups also converts the cyclopropane ring to an excellent electron donor. Although 1-phenyl- and 1,2-diphenylcyclopropane arguably belong into the category of aromatic compounds, their electron-transfer chemistry is included here, because their reactions are essentially those of cyclopropane compounds.

Two types of competing reaction pose potential drawbacks to the PET method. First, the principal types of electron acceptor are ketones and quinones, the triplet states of which are known to abstract hydrogen atoms with formation of neutral radicals. Second, many of the radical cations generated by PET are potential proton

donors (Section 2.2.5) and the radical anions are comparably strong bases. Accordingly, proton transfer in the geminate radical ion pair might produce neutral radicals, and the potential involvement of two or more competing reactions might introduce mechanistic ambiguities. On the other hand, this feature has made it possible to study interesting electron-transfer-proton-transfer sequences.

Electron transfer of cyclopropane systems—the CIDNP method

As mentioned earlier, the cyclopropane radical cation, prepared by γ -radiolysis in rigid matrices, had an ESR spectrum compatible with the trimethylene structure (2A_1) [78, 79]. Irradiation of several methyl-substituted derivatives at 77 K gave rise

to a family of radical cations of the same structure type (type A) [105], which had been identified previously on the basis of chemically induced dynamic nuclear polarization (CIDNP) results [107, 110]. Because of the significance of this method for the study of electron-transfer reactions and for assigning radical cation structures, we briefly discuss the underlying basic principles.

Chemically induced dynamic nuclear polarization (CIDNP) is a nuclear magnetic resonance method based on the observation of transient signals, typically substantially enhanced, in either absorption or emission. These effects are induced as a result of magnetic interactions in radical or radical ion pairs on the nanosecond time scale. This method requires acquisition of an NMR spectrum during (or within a few seconds of) the generation of the radical ion pairs. The CIDNP technique is applied in solution, typically at room temperature, and lends itself to modest time resolution. The first CIDNP effects were reported in 1967, and their potential as a mechanistic tool for radical pair reactions was soon recognized [117, 118]. Nuclear spin polarization effects were discovered in reactions of neutral radicals and experiments in the author's laboratory established that similar effects could also be induced in radical ions [119–121].

The theory underlying this effect depends critically on two selection principles: the nuclear spin-dependence of intersystem crossing in a radical pair, and the electron spin-dependence of the rates of radical pair reactions. The combination of these selection principles causes a 'sorting' of nuclear spin states into different products, formed by geminate recombination (allowed for singlet pairs but spin-forbidden for triplet pairs) or by free-radical ('escape') products (whose formation is electron spin-independent). As a result, geminate reaction products are formed with characteristic non-equilibrium populations of nuclear spin levels, whereas 'escape' products show complementary non-equilibrium spin level populations.

The transitions between levels with non-equilibrium populations will be in the direction towards restoring the normal Boltzmann population; their signal intensities will depend on the extent of non-equilibrium population. The observed effects are optimal for radical pairs with lifetimes in the nanosecond range. On a shorter time-scale, hyperfine induced intersystem crossing is negligible whereas on a longer time-scale the polarization decays owing to spin–lattice relaxation in the radicals.

The quantitative theory of CIDNP enables one to compute the intensity ratios of CIDNP spectra on the basis of reaction and relaxation rates and characteristic parameters of the radical pair (initial spin multiplicity, μ), the individual radicals (electron g factors, hyperfine coupling constants, a), and the products (spin–spin coupling constants, J) [122–126]. Conversely, the patterns of signal directions and intensities observed for different nuclei of a reaction product can be interpreted in terms of the hyperfine coupling constants of the same nuclei in the radical cation intermediate. This feature has proved significant for the assignment of radical cation structures.

In a well designed experiment, the pattern of CIDNP signal directions and intensities observed for a diamagnetic product reveal the relative magnitude and the absolute sign of the hyperfine coupling constants of the corresponding nuclei in the paramagnetic intermediate. The hyperfine coupling constants, in turn, can be interpreted in terms of carbon spin densities and these reveal important structural features of the intermediates. These results often are quite unambiguous, because

Figure 16. PMR spectra (90 MHz) observed during the irradiation of chloranil in acetonitrile- d_3 solutions containing *trans*- (top) or *cis*-1,2-diphenylcyclopropane (bottom), respectively [107].

NMR chemical shifts are usually well understood, and the identity of the coupled nuclei is clearly established. Combined with PET as a method of radical ion generation, the CIDNP technique has been the key to elucidating mechanistic details of important reactions and provided insight into many short-lived radical cations with unusual structures, many of which had previously eluded any other technique.

The nature of the cyclopropane radical cation was first characterized unambiguously by CIDNP effects of a 1,2-disubstituted derivative. The pattern of benzylic and geminal polarization observed during the reaction of chloranil with *cis*- and *trans*-1,2-diphenylcyclopropane (Figure 16) supported radical ions with spin-density on the benzylic carbons [107].

Strictly, the results do not differentiate a priori between a 'closed' and an 'open' radical cation. The 'closed' structure was assigned because the reaction did not cause geometric isomerization, suggesting that the stereochemistry at the key car-

bonds is preserved in the intermediate. These results establish local minima on the radical cation potential surface but do not eliminate the possibility of the existence of additional minima with different stereochemistry and allow no conclusions concerning the global minimum on the radical ion energy surface.

'Standard' structure types of cyclopropane radical cations

In this context we consider the potential effects of substituents on the structure of the cyclopropane radical cation. For molecules with a pair of degenerate HOMOs suitable substitution might be expected to lift the degeneracy and favor one structure over the other. Qualitative predictions of the favored structure can be based on a frontier (F) MO/perturbational (P) MO approach [110, 127]. The substrates are dissected into molecular fragments and the potential interactions of the component FMOs are considered. According to PMO theory [127] the strength of the fragment perturbation is approximately proportional to $S^2/\Delta E$, where S is the overlap integral between the components and ΔE is the difference between the FMO orbital energies. For the S^2 term, three factors will be of primary importance: the FMO orbital symmetry (where present); the magnitude of the coefficients at the point(s) of union; and the orientation of the fragments relative to each other [110].

For cyclopropane, substituents at a single carbon might most effectively stabilize the anti-symmetrical HOMO, whereas substitution at two carbons is expected stabilize the symmetrical orbital. The radical ions of many derivatives also belong to the general structure type **A**. On the other hand, cyclopropane radical cations with the alternative, anti-symmetrical singly occupied (SO) MO should be of particular interest. The reversal of the ordering of structure types **A** and **B** can be envisaged via three different mechanisms, involving stabilization of structure type **B** by conjugation, homoconjugation, or hyperconjugation.

Because a structure of 2A_1 symmetry was established for the prototype [78], it is hardly surprising that the radical ions of many derivatives also belong to that general structure type. Radical cations of the same structure type as those derived from *cis*- and *trans*-1,2-diphenylcyclopropane were established for numerous cyclopropane derivatives, including 1,2-di-, 1,1,2-tri- and 1,1,2,2-tetramethylcyclopropane (Table 4) [104, 109]. Two of these systems provide a direct comparison between the results of CIDNP and ESR experiments. In both instances the ESR spectra observed by Williams and coworkers after γ -irradiation in frozen solutions [105, 106] contain splitting patterns supporting the presence of spin-density on two car-

Figure 17. Minima and transition states on the potential energy surface of radical cation states of 1-methylcyclopropane (PMP4/6-311G*//UMP2/6-31G* + Δ ZPE; relative energies in kcal/mol) [103].

bon centers and, thus, fully confirm the structure type (A) assigned on the basis of CIDNP results.

Stabilization by hyperconjugation was probed by ab initio calculations on the radical cations of methyl- and 1,1-dimethylcyclopropane [103]. Two sets of structures reflect the first-order Jahn–Teller distortion of the parent cation from the doubly degenerate $^2E'$ (D_{3h} symmetry) ground state to non-degenerate states 2A_1 and 2B_2 . States of type A (one long and two short ring C–C bonds) are always minima. For methyl and 1,1-dimethyl derivatives, type B structures are the preferred first-order Jahn–Teller type distorted structures. Although their energies lie below the type A structures, the type B structures are, however, transition states, undergoing second-order Jahn–Teller type distortions to unsymmetrical (scalene) structures with one very long C–C bond. These structures represent the absolute minima for 1-methyl- and 1,1-dimethylcyclopropane radical cations (Figure 17) [103]. The ‘scalene’ structures can be viewed as distorted type B structures or as unsymmetrical type A structures with substituents at one ‘terminal’ carbon.

The calculated hyperfine coupling constants (B3LYP/6-31G*//MP2/6-31G*) for the type B transition state and the distorted minimum clearly show that this species must be considered a type A structure. The hyperfine coupling pattern of the lowest-energy minimum ($a_2 = -1.43$ mT; $a_3 = 1.98$ mT) shows a trend similar to the experimental splittings of the *trans*-1,2-dimethylcyclopropane radical cation ($a_{1,2} = -1.19$ mT; $a_3 = 2.18$ mT), whereas the pattern calculated for the transition state ($a_{2,3} = 0.55$ mT) is incompatible with that model (Figure 18). The distorted structure type calculated for the methyl-substituted systems seems to prevail also under other conditions (see below).

Although the results indicated some stabilization for the type B structures, they clearly indicate that hyperconjugation is not sufficient to alter the ‘natural’ preference of cyclopropane radical cations for the type A structure. On the other hand, both conjugation and homoconjugation have been shown to reverse the stabilities

Figure 18. Comparison between the hyperfine coupling constants calculated for the type **B** radical cation (top, left) and the distorted minimum (top, right), respectively, of 1,1-dimethylcyclopropane [31] and the experimental hyperfine coupling constants [105, 106] of 1,2-dimethylcyclopropane (bottom).

of the 'natural' structure types 2B_2 and 2A_1 . Conjugation with a suitable π -system, either a vinyl [128] or a phenyl group [129, 130], is sufficient to stabilize structures of type **B**, whereas homoconjugation stabilized type **B** radical cations for substrates, such as norcaradiene and derivatives [108, 131] and spiro[cyclopropane-1,9'-fluorene] [110, 132]. These assignments are based on experimental results and born out by ab initio calculations.

The structure of the phenylcyclopropane radical cation, $14^{+\bullet}$, was based on CIDNP effects observed during the electron-transfer reaction from **14** to photo-excited chloranil. The results indicated that the unpaired electron spin was delocalized between the aromatic ring and the benzylic cyclopropane carbon [129]. π,σ -Polarization induces negative hyperfine coupling (hfc) constants in the aromatic *ortho* and *para* protons and in the benzylic cyclopropane protons. The secondary cyclopropane protons had significantly divergent hyperfine coupling constants, because of a pronounced stereoelectronic effect. The strongly polarized secondary protons confirm the presence of spin-density on the benzylic carbon; the emission supports positive hfc's, which arise typically via π,σ -delocalization (hyperconjugation) of spin-density on to the ^1H nuclei. These results support a radical cation, $14^{+\bullet}$, $\text{R} = \text{H}$, in which spin and charge are delocalized between the phenyl ring and the benzylic cyclopropane carbon; two cyclopropane bonds are lengthened and weakened (type **B**). These conclusions are in full accord with the results of ab initio calculations (B3LYP/6-31G*), which delineated the principal structural features and the charge density distribution in the radical cation, $14^{+\bullet}$ [129, 130].

The vinylcyclopropane radical cation, $15^{\bullet+}$, is another radical cation of structure type **B**, which is stabilized by conjugation. Its proposed structure was based exclusively on ab initio calculations (B3LYP/6-31G*) because the electron-transfer photochemistry of this species failed to provide clear-cut CIDNP effects [128]. In this context it is worth noting that product studies cannot, in principle, establish the cyclopropane radical cation structure type. Irrespective of the structure, nucleophilic capture is expected to result in the cleavage of the strained ring.

Calculations using the 6-31G* basis set and employing UB3LYP//UB3LYP and UMP2//UB3LYP methodologies, respectively, indicated the existence of two conformers, *s-anti-1* $^{\bullet+}$ and *s-syn-1* $^{\bullet+}$. Both have structures of type **B**, resembling a π -complex between vinylmethylene and ethene. The calculated bond lengths for the two conformers show similar trends; the allylic cyclopropane bonds are lengthened (+6 %) whereas the bond between the secondary carbons C2–C3 is shortened (–4 %). Also, the distinct difference between the (vinyl) double bond (134.0 pm) and the bond linking the cyclopropane and ethene functions (147.5 pm) is reduced; these bonds are of essentially equal length (139.8); in essence, the array, C β –C α –C1, has been converted to an allyl moiety [128].

The calculated spin densities of the two conformers support the conclusions derived from the bond lengths—most of the unpaired electron density is located on the tertiary cyclopropane carbon (C1) and the terminal vinyl carbon (C β). The general type of spin-density distribution calculated for the two conformers of $15^{\bullet+}$ has precedent in several vinylcyclopropane systems with 'locked' geometries (vide infra) [134, 135].

Perhaps the most interesting mechanism stabilizing radical cations of type **B** involves homoconjugation. The interaction with the butadiene frontier molecular orbital (FMO) can lift the degeneracy of the cyclopropane in-plane e' orbitals (*S*, *A*) and favor the type **B** structure. This principle was shown to stabilize substrates such as norcaradiene and derivatives [110, 131] and, to a lesser extent,

Figure 19. Structures of norcaradiene, **16**, and two derivatives, **17**, **18**, and schematic illustration of homoconjugation between the frontier molecular orbitals of butadiene (bottom left) and styrene (bottom right), respectively, with the anti-symmetrical cyclopropane HOMO.

spiro[cyclopropane-1,9'-fluorene] [110, 132]. The assignments are based on *ab initio* calculations on the parent system (**16**) and two derivatives, on CIDNP results observed for a benzo-annulated system (benzonorcaradiene, **17**), and on the electron-transfer photochemistry of a bridged tricyclic derivative, tricyclo[4.3.1.0^{1,6}]deca-2,4-diene (**18**) in the presence of methanol. This study identified **18** as a unique probe elucidating mechanistic features of the nucleophilic capture of radical cations (Figure 19).

The norcaradiene radical cation, **16**^{•+}, has *C_s* symmetry and a ²A'' electronic ground state. The bond lengths offer limited support for homoconjugation. Although the internal cyclopropane bond of **16**^{•+} (C1–C6 = 153.8 pm) is slightly longer than the two lateral bonds (C1–C7 = C6–C7 = 153.3 pm), it is actually shortened upon ionization (–3.4 pm) while the lateral bonds are lengthened (+2.8 pm). The bonds between the pairs of olefinic carbons (C2–C3 = C4–C5 = 139.5 pm) are only marginally shorter than the intervening bond (C3–C4 = 140.5 pm). However, the delocalization of spin-density to C7 clearly supports the effect of homoconjugation. Although the (UMP2) spin-density at C7 ($\rho_7 = 0.246$) is lower than that at the terminal butadiene carbons, ($\rho_{2,5} = 0.359$), the delocalization of spin and charge on to C7 supports a structure of type **B**. The extent of delocalization depends on the level of perturbation theory; calculations at the UHF level show significantly less delocalization ($\rho_{2,5} = 0.61$, $\rho_7 = 0.231$) than do the UMP2 calculations. The hyperfine coupling pattern also reflects a type **B** structure. Two alkene protons (H2,5) and the geminal cyclopropane protons have significant negative coupling constants ($a_{2,5} = -0.091$ mT; $a_{7\text{syn}} = -0.057$ mT; $a_{7\text{anti}} = -0.063$ mT); sizeable positive cou-

pling constants ($a_{1,6} = 1.36$ mT) are observed for the bridgehead carbons; the alkene protons near the nodal plane have negligible coupling constants ($a_{3,4} = -0.04$ G) [131].

Benzobicyclo[4.1.0]hepta-2,4-diene radical cation, $17^{+\bullet}$ (no symmetry), was optimized at the UHF/6-31G* level of theory. The cyclopropane C–C bonds are subtly different; the lateral bond conjugated with the ethene function (C1–C7, 152.4 pm) is longer, whereas that conjugated with the benzene ring is shorter (C6–C7, 149.1 pm), than the internal bond (C1–C6, 151.3 pm). The bonds linking the strained ring to the styrene moiety are slightly longer (C1–C2, 145.4 pm; C5–C6, 148.5 pm) than those of the styrene function (C2–C3 138.5 pm; C4–C5 143.8 pm; C3–C4 139.9 pm) [131].

The assignment of an antisymmetric cyclopropane SOMO to the radical cation, $17^{+\bullet}$, was based on a comparison of CIDNP effects (Figure 20) with those for *cis*-1,2-diphenylcyclopropane. While the nuclei of the aromatic segments showed identical or very similar polarization, the cyclopropane protons show characteristic differences. This suggests significantly different spin-density distributions for the cyclopropane moieties of the two species and, thus, different structures [108]. The benzonorcaradiene radical cation should owe its structure to the symmetry of the fragment FMOs at the points of union. The styrene HOMO is antisymmetric at the positions of attachment, suggesting preferred interaction with the antisymmetric cyclopropane HOMO (Figure 19).

The calculated carbon spin densities of $17^{+\bullet}$ document the extent of homoconjugation; most of the spin is located on C2 ($\rho_2 = 0.355$), significantly less on C5 and C7 ($\rho_5 = 0.153$, $\rho_7 = 0.149$), whereas the tertiary cyclopropane carbons, C1 and C6 ($\rho_1 = -0.009$, $\rho_6 = -0.007$), have negative spin-density. The calculated hfcs are in qualitative agreement with the CIDNP effects observed during the electron transfer from benzonorcaradiene, **17**, to photo-excited chloranil [108]. The tertiary cyclopropane ^1H nuclei, H1 and H6, have large positive hfcs ($a_1 = 0.93$ mT, $a_6 = 1.06$ mT), whereas the geminal cyclopropane nuclei ($\text{H}_{7\text{s,a}}$), have negative hfcs of moderate magnitude ($a_{7\text{s}} = -0.34$ mT, $a_{7\text{a}} = -0.28$ mT) [131].

Tricyclo[4.3.1.0^{1,6}]deca-2,4-diene radical cation, $18^{+\bullet}$, also has a $^2A''$ electronic ground state. When optimized at the UHF/6-31G* level of theory with imposed C_s symmetry. The C–C bond lengths of the cyclopropane ring are slightly more divergent than are those of $16^{+\bullet}$; the internal bond (C1–C6 = 153.9 pm) is 3 pm longer than the lateral bonds (C1–C10 = C6–C10 = 150.8 pm). Both types of bonds are lengthened upon ionization, perhaps due to the release of strain. The bonds between the olefinic carbons are essentially equal in length (C2–C3 = C4–C5 = 139.3 pm; C3–C4 = 139.1 pm) [131].

The carbon spin-density on the bridge carbon is lower than that of $16^{+\bullet}$ ($\rho_{10} = 0.203$), even considering the lower level of theory, whereas the terminal butadiene carbons have correspondingly higher spin densities ($\rho_{2,5} = 0.383$). The hyperfine coupling pattern of $18^{+\bullet}$ shows minor changes relative to $16^{+\bullet}$: increased coupling constants for the olefinic protons $\text{H}_{2,5} = -0.96$ mT) and decreased coupling constants for the cyclopropane protons ($a_{10\text{syn}} = -0.54$ mT; $a_{10\text{anti}} = -0.48$ mT). These data support a radical cation related to structure type **B**. The extent of homoconjugation, as judged by the extent of delocalization, is less than for $16^{+\bullet}$, possibly

Figure 20. ^1H CIDNP spectra (cyclopropane resonances only) observed during the photo-reaction of chloranil with *cis*-1,2-diphenylcyclopropane (top) and benzonorcaradiene (bottom). The opposite signal directions observed for analogous protons provide evidence that the two radical cations belong to two different structure types [107, 108].

because of strain introduced by the trimethylene bridge. This feature, though crucial for enforcing the norcaradiene structure, might limit the extent of homoconjugation because of steric factors. Still, the calculations predict a significant role of homoconjugation in the radical cations, $16^{\bullet+}$ and $18^{\bullet+}$.

The radical cation of spirofluorene, **19**, is mentioned only in passing. The orientation of the fragments allows only the second highest MO of the biphenyl moiety to interact with a cyclopropane FMO (the *A* HOMO). Thus, the type B structure should be stabilized to a lesser extent. The extent of homoconjugation also is expected to be weak because of a more serious mismatch in orbital energies [110, 127].

The interaction between a cyclopropane group and olefinic or aromatic systems conjugated to it depends on their relative orientation. Although the 3°,3°-cyclopropane bond of benzonorcaradiene (**17**) lies in a plane perpendicular to the aromatic π system, [1:2,9:10]bismethano[2.2]paracyclophane (**20**) features a parallel arrangement of these elements [133]. The photoreaction of this obviously strained compound with chloranil gives rise to CIDNP effects not unlike those observed for *cis*-diphenylcyclopropane (*cis*-**13**). The relative signal intensities of **20** are, however, noticeably distorted (Figure 21). The (secondary) endo proton (1.2 ppm) is more strongly enhanced (indicating a larger hyperfine coupling) than both the *exo* (2.0 ppm) and the benzylic protons.

Figure 21. A comparison of the CIDNP effects observed for the cyclopropane protons of *cis*-diphenylcyclopropane (left) and [1:2,9:10]bismethano[2.2]paracyclophane (right) [133].

Figure 22. Partial view of [1:2.9:10] bismethano[2.2]paracyclophane showing the angles Φ and Θ discussed in the text.

This finding was interpreted in terms of different dihedral angles, Θ_x and Θ_n , between the singly occupied orbital and the two geminal C–H bonds. Non-identical dihedral angles for the secondary cyclopropane protons can result if the angle, Φ (Figure 22), and the distance between the benzylic cyclopropane carbons is increased in the radical cation relative to the parent hydrocarbon. The endo proton, which in the diamagnetic molecule lies in the shielding cone of the aromatic moieties, has in the radical cation the smaller dihedral angle Θ , with the benzylic ‘ π ’ orbital (Figure 22) and, therefore, the greater hyperfine coupling [133].

The comparably weak enhancement of the benzylic protons and the relatively strong ^{13}C polarization for the benzylic carbons are indicative of a pyramidal benzylic carbon. Although radicals containing pyramidal carbon are reasonably rare, existing examples are derived from strained ring systems [136–139]. For the radical cation $20^{+\bullet}$, the change in the angle, Φ , the stretching of the doubly benzylic bond, and the adoption of a pyramidal structure apparently relieve some of the strain in the carbon skeleton, yet maintain reasonable overlap between the benzylic carbons and the benzene rings [133]. Possibly, the sum of these changes may amount to a ‘ring-opened’ cyclopropane radical cation (*vide infra*).

Electron transfer and ring-opening—trimethylene radical cation

The potential ‘ring-opening’ of cyclopropane radical cations, ‘breaking’ the weakened bond of type A radical cations ($21^{+\bullet}$), has been a subject of both interest and controversy. The ESR spectra of cyclopropane radical cation and its methyl-substituted derivatives decayed at temperatures near 100 K. They were replaced by secondary spectra, in which the protons at one cyclopropane center do not interact with the electron spin. This coupling pattern was interpreted as evidence for a ring-opened trimethylene species ($22^{+\bullet}$) in which one terminal carbon has rotated into an orthogonal orientation [105, 106, 140].

Similar species were postulated to explain the geometric isomerization of 1-aryl-2-vinylcyclopropanes upon reaction with aminium radical cations [141]. As mentioned above, *ab initio* calculations fail to support the existence of this structure type for the parent system and simple derivatives. Another potential argument against the existence of species such as **22^{•+}** lies in its failure to undergo a hydrogen shift, generating the known and stable propene radical cation [142]. Hydrogen shifts have been observed in numerous electron-transfer-induced reactions [143–147], including in matrices at cryogenic temperatures, under the very conditions that give rise to the putative **22^{•+}** [143–146]. These considerations have led several authors to advance alternative explanations. They include structures, such as **23[•]** [99–101, 148], in which a chloride ion has captured the cationic center of either **21^{•+}** or **22^{•+}**. Although interaction of **21^{•+}** or **22^{•+}** with one or more matrix molecules might form a chloronium-substituted free radical or a matrix cluster [149], ESR spectra failed to furnish direct evidence for coupling to the matrix.

Interestingly, the rearrangement was found to be limited to two matrices, $\text{CFCl}_2\text{CF}_2\text{Cl}$ and $\text{CF}_2\text{ClCF}_2\text{Cl}$, suggesting a major role of the matrix in the conversion. The putative nucleophilic ring opening by chloride ion, generating the β -chloroalkyl radical (**23[•]**), has precedent in many substitution of cyclopropane radical cations in solution (Section 2.4.3). In this instance the matrix might prevent the approach of the ion. Comparison of radical cation structures or reactions in matrices and in solution can, however, be misleading. Matrix forces are responsible for several reactions unprecedented in solution, such as the series of ‘fragmentations’ in zeolites (Section 2.2.7). Matrix forces have been invoked also to account for a ‘reordering’ of electronic states in matrices (Section 2.2.6) or zeolites (Section 2.4.2). In view of these considerations the discrepancy between the postulated structure (**22^{•+}**) and the *ab initio* calculations is unsettling but not irreconcilable.

In this context, we mention two zeolite-induced conversions of cyclopropane derivatives. Incorporation of *trans*-1,2-diphenylcyclopropane (*trans*-**13**) and its 3,3-D₂-isotopomer into the channels of a redox-active pentasil zeolite (Na-ZSM-5) generated *exo,exo*-1,3-diphenylallyl radical (**24[•]**) and its 2-D₁-isotopomer. This conversion is a zeolite-specific reaction; it requires a series of reactions, including oxidation, ring opening, and deprotonation [70].

Incorporation of arylcyclopropanes (**25**, R = H, OCH₃) into ZSM-5 also caused a matrix-specific conversion, generating *trans*-propenylbenzene radical cations

($26^{+\bullet}$, $R = H, OCH_3$) [70]. The formation of $26^{+\bullet}$ requires a series of reactions, including oxidation, ring opening, and a hydrogen shift. Interestingly, the 2,2- d_2 -isotopomer of **25** ($R = OCH_3$) gave rise to three different isotopomers of $26^{+\bullet}$ ($R = OCH_3$), containing two, one or no deuterium. This observation requires several competing mechanisms, including one proceeding with two D vs. H exchanges. This reaction also is zeolite-specific.

Ring-opened cyclopropane radical cations have been postulated also to account for the stereochemistry of the aminium radical cation-catalyzed rearrangement of 1-aryl-2-vinylcyclopropanes (**27**) [141]. These systems, of course, contain substituents that might veil the ‘true’ nature of the cyclopropane radical cation by delocalizing spin and charge.

The potential surface of the radical cations derived from **27** might contain several minima separated by low barriers; the ultimate reaction products might afford little information about any one minimum. Even ESR results might not differentiate unambiguously between a planar ring-opened radical cation ($29^{+\bullet}$) and a rapidly equilibrating pair of orthogonal bifunctional intermediates (e.g., $28^{+\bullet}$). Perhaps the most likely explanation involves a pair of isomeric cyclopropane radical cations with one very weak bond, viz., $27^{+\bullet}$, which might enable either or both tertiary carbon atoms to rotate. The bifunctional structures shown below, either orthogonal (e.g. $28^{+\bullet}$) or planar ($29^{+\bullet}$) might signify minima or transition structures.

Additional insight into the ‘ring-closed’ or ‘ring-opened’ structure of cyclopropane radical cations can be derived unambiguously from the stereochemical course of their reactions. These reactions are discussed in detail in Section 2.4; here we briefly mention several illuminating examples of cyclopropane radical cation reactivity, chosen solely to illuminate the structure of cyclopropane radical cations.

Various substituted cyclopropanes undergo electron-transfer-induced nucleophilic addition of alcoholic solvents. For example, the electron-transfer reaction of phenylcyclopropane (**30**, $R = H$) with *p*-dicyanobenzene resulted in a ring-opened ether, **31** [150]. This reaction also produced an aromatic substitution product (**32**, $R = H$) formed by coupling with the sensitizer anion [150–152]. A related pair of products (**31**, **33**, $R = H$) was obtained upon photo-induced electron transfer between phenylcyclopropane and *N*-methylphthalimide [153].

More recently, Dinnocenzo and colleagues showed that a 2,3-dimethyl derivative (**30**, $R = CH_3$) and several 1-phenyl- and 1,1-diphenyl-2-alkyl-substituted cyclopropanes are captured with complete inversion of configuration [154, 155]. The observed stereochemistry requires an intermediate radical cation, $30^{+\bullet}$, with the unperturbed stereochemistry of the parent molecule. This result unambiguously rules out a ring-opened cyclopropane radical cation in solution.

The nature of vinylcyclopropane radical cation was elucidated via the electron-transfer photochemistry of a simple vinylcyclopropane system, in which the two functions are locked in the *anti* configuration, viz. 4-methylene-1-isopropylbicyclo-[3.1.0]hexane (sabinene, **34**) [156]. The electron-transfer reaction of (1*R*, 5*R*)-(+)-**34** with 1,4-dicyanobenzene–phenanthrene in acetonitrile–methanol produced various optically active ring-opened products. The stereochemical relationship between **34** and the products requires that the radical cation, $34^{+\bullet}$, retain the three-dimensional integrity of **34**, i.e., that significant bonding is maintained in the three-membered ring. Any ring-opened radical cation, in which C1 would be planar, is clearly eliminated. Nucleophilic capture of $34^{+\bullet}$ by methanol generated free radical **35** $^{\bullet}$ in stereoselective fashion. In competition with this intermolecular reaction, an intramolecular hydride shift from C6 to C1 produced β -phellandrene radical cation, $36^{+\bullet}$, which is also captured by the nucleophile.

2.3.3 Electron-transfer Reactions of Substituted Cyclobutane Systems

Having discussed the electron-transfer reactions of cyclopropane derivatives in some detail, we only touch briefly on the related reactions of the larger ring systems. Cyclobutane, cyclohexane, and cyclooctane have degenerate HOMOs (Section 2.3.1); thus, their radical cations are Jahn–Teller active. It is reasonable to expect that suitable substitution will lift the degeneracy and favor one radical cation structure over the other. Qualitative predictions of the preferred structure are readily derived.

Considering cyclobutane, one might expect that 1,2-disubstituted derivatives favor structure type C, in which the doubly substituted cyclobutane bond is weakened (and lengthened), or a related structure type, in which this bond is actually broken. Ab initio calculations at the QCISD-(T)/6-31G*//UMP2/6-31G* level of theory showed that the radical cation of *trans*-1,2-dimethylcyclobutane has a trapezoidal structure [86]. Although ESR results on simple derivatives are not available, this expectation is born out by several experimental observations.

For example, the electron-transfer-induced geometric isomerization of 1,2-diaryloxycyclobutane, **37**, can be rationalized via the bifunctional radical cation, **38**^{•+}, formed by ring opening of a type C radical ion [157]. Similarly, the fragmentation of the *anti*-head-to-head dimer of dimethylindene might involve consecutive cleavage of two cyclobutane bonds in a type C radical ion. Because of the low ionization potential of the aryl substituents (*IP* 9.25 eV) [8], the primary ionization is expected to occur from one of the aryl groups. CIDNP results observed during the dimer cleavage were rationalized in terms of an equilibrium between ring-closed (**39**^{•+}) and ring-open (**40**^{•+}) radical cations [158].

By analogy with substituent effects discussed for the cyclopropane system (Section 2.3.2), one might expect that 1,1-disubstitution might stabilize cyclobutane radical cations of the structure type resembling a kite (type D). As far as we are aware such a structure has not yet been established unambiguously, although the oxetane radical cation (**41**^{•+}) clearly belongs to that structure type. The unpaired electron is localized on the oxygen and the adjacent ¹H nuclei are strongly coupled ($a = 6.6$ mT, $a = 1.1$ mT) [159, 160].

Cyclobutane radical cations can also be formed by addition of ethylene radical cations to a neutral ethylene. For example, vinyl amines [161] and other electron-rich alkenes [162] undergo [1 + 2] cycloadditions, which even might proceed as chain reactions [163]. Fluorescence-detected magnetic resonance effects observed during the pulse radiolysis of anthracene-d₁₀ in the presence of tetramethylethene generated an ESR spectrum compatible with eight equivalent methyl groups; the splitting, $a_d = 0.82$ mT, was approximately one half that of the monomer splitting, $a_m = 17.1$ mT [164–167]. The data were interpreted as evidence for a ‘sandwich’ dimer; higher cluster cations were also invoked [167]. Although the ESR spectrum is compatible with a radical cation with two weakened C–C bonds (type A; **42**^{•+}), they do not rule out other structures.

Ab initio calculations at the QCISD-(T)/6-31G**/UMP2/6-31G* level of theory failed to furnish evidence for the ‘sandwich-type’ π -complex; rather, they support the formation of an ‘*anti*’- π -complex between ethylene and its radical cation, in which the two components are connected by one long (190 pm) bond only. This complex is connected to two different transition states leading to the (rhombic) cyclobutane radical cation or, by 1,3-H-shift, to 1-butene radical cation [167].

The density functional theory calculations mentioned earlier also modeled the ring-opening of cyclobutane radical cation [87]. This reaction proceeded via a distorted trapezoid transition state with two shorter (142.2, 147.1 pm) and two longer bonds (187.7, 208.4 pm), forming the ‘*anti*’-complex (one long bond; 227.6 pm), similar to that calculated earlier [168].

As for derivatives of unstrained ring systems, we mention—in passing—the electron-transfer oxidation of various mono-, di-, or trialkylcyclohexanes, which were studied in significant detail. Interestingly, the radical cations of 1-alkyl and 1,1-dialkyl derivatives have been assigned a SOMO resembling the a_g SOMO of the cyclohexane radical cation [169–171]. A more detailed discussion would exceed the scope of this review.

2.3.4 Electron-transfer Reactions of Cycloalkanes in Zeolites

Similar to linear and branched alkanes, cycloalkanes also give rise to radical cations in zeolites, spontaneously or upon γ -radiolysis. This brief discussion of selected examples is intended only to give a flavor of the work being done. Thus, a 13-line radical cation spectrum ($a = 0.17$ mT, $g = 2.003$) obtained upon incorporation of 1-methylcyclohexane, **43**, into zeolites [71] was identified as 1,2-dimethylcyclopentene radical cation, **44** $^{\bullet+}$ (two sets of protons with hyperfine coupling constants in the ratio of ca 2:1; $a = 1.67$ mT, 2 CH_3 ; $a = 3.42$ mT, 4H) [72]. The formation of **44** $^{\bullet+}$ was rationalized by protonation of the 3° carbon of **43**, followed by loss of H_2 . Loss of a proton from a rearranged carbocation may generate **44**, which is oxidized to **44** $^{\bullet+}$ by a Lewis site.

γ -Irradiation of cyclohexane on Na-ZSM-5 at 77 K generated the EPR spectrum of cyclohexyl free radical, **45** \cdot [172]. The clear difference between two sets of β -protons ($a = 2.2$ mT, $1H_{\alpha}$; $a = 4.0$ mT, $2H_{ax}$; $a = 0.5$ mT, $2H_{eq}$) indicates that at 77 K **45** \cdot is conformationally rigid. A cyclohexane radical cation (Section 2.3.1) is a probable intermediate, but no evidence for this species was observed. The formation of **45** \cdot was ascribed to 'spontaneous' proton transfer to the zeolite matrix, in contrast with previously discussed deprotonations (Section 2.2.5), which proceeded by ion-molecule reactions.

γ -Radiolysis of 1,1,2,2-tetramethylcyclopropane, **21**, in zeolite Na-Y produced an EPR spectrum that was simulated with the known hyperfine coupling parameters of radical cation, **21** \cdot^+ , with one lengthened cyclopropane bond (Section 2.3.4; $a = 1.87$ mT, $2H$; $a = 1.49$ mT, $12H$) [173]. In contrast with *trans*-1,2-diphenylcyclopropane (*trans*-**13**), which is spontaneously oxidized and undergoes ring opening and deprotonation (below), **45** \cdot^+ remains unchanged. Apparently, its bulky shape isolates it from other molecules as well as precluding migration in the channels.

2.4 Electron-transfer Reactions of Bicyclic Systems

Many bicycloalkanes are as unreactive as alkanes or unstrained cycloalkanes. They have very high pK_a values and their low electron affinities make them poor electron acceptors. The ionization potentials of unstrained bicycloalkanes are somewhat lower than those of unstrained cycloalkanes—bicyclo[2.2.2]octane (*IP* 9.47 eV), bicyclo[4.3.0]nonane (*IP* 9.46 eV), or bicyclo[4.4.0]decane (*IP* 9.32 eV) lie below the 9.75–9.90 eV range characteristic of cycloalkanes [5]. As a result, they are somewhat easier to oxidize in solution or in solid matrices. Strained bicycloalkanes have even lower ionization potentials (bicyclo[1.1.0]butane, *IP* 8.7 eV); the ring strain

present in these systems provides an additional driving force for their oxidation, making them significantly better electron donors. As a result, they readily undergo photo-induced electron transfer to excited electron acceptors in solution. All bicycloalkanes are readily ionized upon electron or He_α impact in the gas phase. Because of the difference in reactivity, we will discuss strained bicycloalkanes separately from those with little or no strain.

2.4.1 Electron Transfer of Strained Bicyclic Systems

Bicyclic ring systems containing three or four-membered rings have special bonding forces, which are reflected in their unusual chemistry. Their electron-transfer reactions have been studied in the gas, liquid, and solid phases, and the structure and reactivity of their radical cations have been the target of intense scrutiny.

Bicyclobutane radical cations

The unique bonding in bicyclobutane, **46**, and its unusual chemistry resulted in early interest in its radical cation. The structure and reactivity of the parent radical cation and of various derivatives have been studied by ESR–ENDOR spectroscopy and CIDNP effects, by identification of representative reaction products, and by MNDO and ab initio calculations. The structure of the bicyclobutane radical cation was characterized by ESR–ENDOR spectroscopy [174–176]. The ESR spectrum contained a triplet (7.7 mT) of quintets (1.14 mT). These results were interpreted in terms of a radical cation, **46** $^{\bullet+}$, in which the bridgehead carbons bear spin-density and the transannular bond is lengthened. Given this spin-density distribution, the large hyperfine coupling was assigned to the axial protons (H_{ax}); the smaller quintet splitting suggests that the remaining two pairs of protons have identical hyperfine couplings. The bridgehead protons have negative coupling constants, because they are adjacent to centers of major spin-density, whereas the axial and equatorial protons (H_{eq}) must have positive hyperfine couplings, as a result of ' π, σ -delocalization'. The large difference between axial and equatorial hyperfine coupling indicates a non-planar, puckered geometry for the radical cation. No evidence for interconversion is apparent up to 160 K; this finding requires an inversion barrier of at least 12 kJ mol $^{-1}$.

MNDO calculations [174, 175] identified the highest occupied MOs (Figure 23). The key feature of the HOMO is a bonding contribution to the transannular link-

Figure 23. Schematic representation of two high lying MOs for bicyclobutane (top) and structure parameters of the bicyclobutane radical cation.

age. Removal of an electron from this HOMO yields radical cation, $46^{+\bullet}$, with a lengthened transannular bond (178.6 pm, MNDO; 174.3 pm, B3LYP/6-31G*//MP2/6-31G*) and an increased flap angle (132° , MNDO; 133.6° , B3LYP/6-31G*//MP2/6-31G*; Figure 23). Coupling constants calculated at different levels of theory are summarized in Table 5.

The photoreactions of electron acceptors with several bridged bicyclobutane systems, e.g., tricyclo[4.1.0.0^{2,7}]heptane, $47^{+\bullet}$, give rise to CIDNP effects supporting negative hfcs for H1 and H7 and positive hfcs for H2 and H6 and for H3,3' and H5,5'. These results would place electron spin-density at C1 and C7, in agreement with the involvement of the A_1 type HOMO (Figure 23) [77, 177]. The axial 'flag-pole' ^1H nuclei of $46^{+\bullet}$ are replaced in $47^{+\bullet}$ by the trimethylene bridge. This structure type has been confirmed by CIDNP results for several derivatives [177, 178].

Although radical cation $47^{+\bullet}$ is persistent in solution on the nanosecond time-scale, both $47^{+\bullet}$ and dihydrobenzvalene radical cation, $48^{+\bullet}$, the lower homolog
